Henry Arthur Cassebeer, Jr., M.D., to Mrs. Eleanor Genevieve Paeake, both of New York City, in London, England, September 29.

Deaths

Harry Dorr Niles, M.D. Medical College of Ohio, Cincinnati, 1880; a member of the American Medical Association; in 1907, president of the Utah Medical Society; formerly president of the Western Surgical and Gynecological and Rocky Mountain Inter-State Medical associations; chief-of-staff of the Holy Cross Hospital, Salt Lake City; Utah; an honorary member of the state associations of Colorado and Idaho; *died at his home in Salt Lake City, September 28,* from cerebral hemorrhage, aged 53. The Salt Lake Medical Society, Salt Lake County Medical Society, and medical staff of the Holy Cross Hospital, at special meetings, adopted resolutions of regret and condolence.

George Edward Post, M.D. New York University, New York City, 1850; dean of the faculty of the Syrian Protestant College, Beyrout, Syria, Asia Minor; professor of surgery in the Syrian Protestant Hospital; and surgeon of the Johanniret Hospital, Beyrout; whose work in the medical missionary field won for him the decoration of the Osmanieh from the Sultan of Turkey, and of the Red Eagle and Knights of Jerusalem from Germany; author of text-books on botany, zoology, physiology, surgery, and materia medica, primarily for the use of his students; died in Beyrout, September 30, aged 70.

Christopher James Cleborne, M.D. University of Pennsylvania, Philadelphia, 1860; rear admiral U. S. Navy, retired; who entered the Navy in May, 1861, served through the Civil War, and during the Spanish-American War was in command of the U. S. Naval Hospital, Norfolk, Va.; served on sea duty for ten years and eight months, and on shore duty for twenty-five years and five months; was retired November 10, 1899 for incapacity resulting from incident of service; died at his home in Washington, D. C., October 2, aged 71.

Pasquale DeCunto, M.D. University of Naples, Italy, 1898; a member of the Colorado State Medical Society; a prominent Italian physician of Denver; who on account of his work in behalf of his fellow-countrymen was made a chevalier of the Order of the Crown of Italy by the King; died at the home of his mother-in-law in Brooklyn, N. Y., October 6, from bronchitis, aged 43.

John Joseph Quirk, M.D. Rush Medical College, Chicago, 1888; a member of the American Medical Association; adjunct professor of skin and venereal diseases in the College of Physicians and Surgeons, Chicago, and the Chicago Clinical School, secretary of the local board of U. S. Pension Examining Surgeons; died at his home in Chicago, October 4, aged 44.

John Newton Gregg, M.D. University of Michigan, Ann Arbor, 1862; of Whittaker, Mich.; professor of anatomy in his alma mater from 1862 to 1864; surgeon of the Twenty-fifth Volunteer Infantry during the Civil War; died at the home of his nephew in Fond du Lac, Wis., September 28, from heart disease, aged 73.

Daniel A. Smith, M.D. Eclectic Medical Institute, Cincinnati, 1855; surgeon of the Twenty-second Georgia Infantry, C. S. A., during the Civil War; mayor of Butler, Ga., and afterward state senator; later mayor of Anthony, Fla., and a member of the legislature; died recently at his home in Anthony, aged 79.

Henry A. Eidson, M.D. Rush Medical College, Chicago, 1880; a member of the Illinois State Medical Society; and of the local board of U. S. pension examining surgeons; died suddenly, while making a professional call at his home in Willow Hill, October 7, from hemorrhage, aged 62.

Charles Horace Evans, M.D. Homeopathic Medical College of Pennsylvania, Philadelphia, 1869; of Chicago; from 1897 to 1904, lecturer on materia medica in Hahnemann Medical College; died in Union Hospital, Chicago, October 4, after an operation for carcinoma of the stomach, aged 62.

Harold Verne Noyes, M.D. Medical School of Maine, Brunswick, 1881; a member of the York County (Maine) Medical Society; for many years superintendent of schools of Berwick; died at his home in Berwick, January 25, from cirrhosis of the liver, aged 50.

Charles Alonzo Cordiner, M.D. Baltimore (Md.) Medical College, 1901; of Portland, Ore.; formerly of Astoria, Ore., and secretary of the Clatsop County Medical Society; died in the Good Samaritan Hospital, Portland, September 25, from spinal meningitis, aged 29.

James Fulton, M.D. Jefferson Medical College, Philadelphia, 1859; a member of the Medical Society of the State of Pennsylvania; one of the oldest practitioners of Chester county; died at his home in New London, September 28, from angina pectoris, aged 77.

Edward Pierson Nicholson, M.D. University of Nashville, Tenn., 1861; a member of the Medical Association of the State of Alabama; died at his home in Valley Head, September 29, from the effects of aconite, taken by mistake for cough syrup, aged 74.

Ludwig Kohn, M.D. University of Vienna, Austria, 1887; a member of the Medical Society of the State of New York; died at his home in New York City, October 4, from the effects of carbolic acid, taken in mistake for a nerve tonic, aged 45.

Charles Parsons Beaman, M.D. New York Homeopathic Medical College, New York City, 1882; a member of the American Medical Association; physician to Cornell University Athletic Association, Ithaca, N. Y.; died October 6, aged 49.

Junius Kincaide Battle, M.D. Tulane University, New Orleans, 1883; a member of the Medical Association of the State of Alabama; city physician of Eufala, Ala.; died at his home in that city, September 28, from cerebral hemorrhage, aged 48.

Otto Frankenberg, M.D. Starling Medical College, Columbus, Ohio, 1870; for twenty years a member of the faculty of his alma mater; died at his home in Grand View, Columbus, September 29, from disease of the bladder, aged 63.

Julian Branch, M.D. Detroit (Mich.) College of Medicine, 1905; of Otisville, Mich.; a member of the Michigan State Medical Society; died in Harper Hospital, Detroit, after an operation for appendicitis, September 30, aged 32.

Charles Frederick Ferguson, M.D. Queen's University, Kingston, Ont., 1859; formerly member of Parliament for Leeds and Grenville, Ont.; died suddenly at his home in Kemptville, Ont., October 1, aged 76.

Riley S. Lycan, M.D. Homeopathic Hospital College, Cleveland, Ohio, 1880; a member of the Illinois State Medical Society; died at his home in Paris, October 2, from pulmonary tuberculosis, aged 54.

Russell Clute, M.D. Albany (N. Y.) Medical College, 1903; of Maplewood, N. J.; physician to Christ's Hospital, Jersey City; died at the home of his sister in Amsterdam, N. Y., September 24, aged 33.

William Alexander Brooks, M.D. Jefferson Medical College, Philadelphia, 1850; a retired practitioner of San Antonio, Texas; died at a local sanitarium, September 18, from senile debility, aged 84.

Ernest Clark Gwinn, M.D. College of Physicians and Surgeons, Chicago, 1906; formerly of Sadorus and Paris, Ill.; died in Monrovia, Cal., from pulmonary tuberculosis, September 9, aged 28.

Joseph S. Biggart (license, Tenn., 1889); an eclectic practitioner of Carroll county, Tenn.; died at his home near Carter's Chapel, recently, and was buried September 26, aged 63.

Isaac M. Mulholland (license, Ohio, years of practice, 1896); for sixty-two years an eclectic practitioner; died at his home in Toledo, June 21, from edema of the lungs, aged 85.

H. F. McCoy, M.D. Columbus (Ohio) Medical College, 1879; formerly of Chauncey, Ohio; died at his home in Harper, Kan., from disease of the kidney recently, and was buried October 3.

William Turner Nolen, M.D. Hospital College of Medicine, Louisville, Ky., 1890; a member of the New Mexico Medical Society; died at Los Tanos, July 14, from tetanus, aged 40.

William A. Childress, M.D. Medical College of Georgia, Augusta, 1858; a Confederate veteran; and a pioneer citizen of Atlanta, Ga.; died at his home, October 1, aged 73.

James Lawson Davis, M.D. University of Alabama, Mobile, 1874; postmaster of Lafayette, Ala.; died at his home, September 12, from strangulated ventral hernia, aged 63.

Jabez Parkhurst Bidwell, M.D. Albany (N. Y.) Medical College, 1860; died at his home in Morrisonville, N. Y., March 17, 1908, after an illness of twelve years, aged 71.

Edmond B. Towne (license, practitioner, Iowa, 1887); since 1876 a practitioner of Coon Rapids, Iowa; died at the home of his son in that city, September 9, aged 80.

John Campbell Buell, M.D. University of Michigan, Homeopathic College, Ann Arbor, 1892; died at his home in Rives Junction, Mich., September 25, aged 39.

Albert Thibodeau, M.D. Laval University, Montreal, 1881; of Escanaba, Mich.; died in the Delta County Hospital, February 13, from carcinoma, aged 49.

Lewis E. Powell, M.D. Atlanta College of Physicians and Surgeons, 1899; died at his home in Waynesboro, Ga.; September 26, from heart disease.

George Harold Grigsby, M.D. University of Louisville (Ky.), 1909; died at his home in West Baden, Ind., September 11, from typhoid fever, aged 26.

Henry B. C. Harris, M.D. New York University, New York City, 1848; died at his home near Wallace, Mo., May 1, from senile debility, aged 83.

Isaac W. Lewis, M.D. Castleton (Vt.) Medical College, 1848; died at his home in Apalachian, N. Y., September 19, aged 88.

Lute B. Irwin, M.D. University of Louisville, Ky., 1858; died at his home in Savannah, Tenn., September 29.

Joseph Francis Xavier Poitras (license, Mass.); died at his home in Brockton, Mass., October 3.

Brazil: Para, Aug. 28-Sept. 7, 9 cases, 6 deaths.

CHOLERA—INSULAR

Philippine Islands: Manila, Aug. 14-28, 3 cases, 2 deaths; Provinces, 342 cases, 246 deaths.

CHOLERA—FOREIGN

China: Amoy, Aug. 14-28, 39 deaths; Hankow, Aug. 18-25, 2 deaths.
India: Bombay, Aug. 18-31, 92 deaths; Calcutta, Aug. 7-21, 11 deaths; Madras, Aug. 14-20, 1 death; Rangoon, 6 deaths.
Japan: Karatsu, Sept. 1, 2 cases, on steamship Tain Maru; Mitajiri Aug. 22, 21 cases.
Korea: Sept. 2, epidemic in the northern part.
Manchuria: Liaoyang, Aug. 10-14, 1 death; Mukden, 1 death; Tashichiao, 1 death; Yinkou, 6 cases, 1 death.
Russia. general, Sept. 3-10, 716 cases, 257 deaths, Sept. 11-17, 946 cases, 251 deaths; St. Petersburg, Sept. 3-10, 167 cases, 45 deaths, Sept. 11-17, 246 cases, 87 deaths.

PLAGUE

Chile: Iquique, Aug. 18-Sept. 5, 6 cases in lazaretto.
China: Amoy, Aug. 14-28, 105 deaths; Hongkong, Aug. 14-21, 1 case, 1 death.
India, general, Aug. 14-21, 1,821 cases, 1,376 deaths; Bombay, Aug. 18-31, 64 deaths; Calcutta, Aug. 7-21, 31 deaths; Rangoon, Aug. 14-21, 28 deaths.
Japan: Kobe, Aug. 29-Sept. 4, 5 cases, 2 deaths.
Peru, general, Aug. 28-Sept. 4, 13 cases, 9 deaths.
Zanzibar: Zanzibar, July 23-24, 2 deaths.

Marriages

George A. Downs, M.D., to Mrs. Ella Thomas Seiling, both of Spokane, Wash., September 18.

Horace L. Husted, M.D., Muscatine, Iowa, to Miss Mabel Merritt, of Iowa City, September 22.

Herman Winford Bundy, M.D., Sadorus, Ill., to Miss Edith Stone of Tolono, Ill., September 29.

William James Swift, M.D., Chicago, to Miss Florence Josephine Lang, of Berlin, Ont., October 6.

Albert V. N. Hennessy, M.D., to Miss Marie Cornelius, both of Council Bluffs, Iowa, September 29.

Edward E. Nathan, M.D., Chicago, to Miss Julia Goldberg, of Deadwood, S. D., in Chicago, October 1.

Alfred Nicholas Murray, M.D., to Miss Edna Auretta Schmidt, both of Chicago, September 30.

Louis Edmunds Guy, M.D., to Miss Anna Thea Louise von N. Rosenegk, at Richmond, Va., September 28.

Archibald G. Thomson, M.D., to Mrs. Mary L. W. Wanamaker, both of Philadelphia, September 29.

Lansing Y. Lippincott, M.D., Metuchen, N. J., to Miss Louise W. Cragin, of New York City, September 22.

Sims Seward Hindman, M.D., Glen Olden, Pa., to Miss Anna Maryland Larimore, of Seaford, Del., October 2.

Rogers M. McCowan, M.D., Knoxville, Tenn., to Miss Nellie Tittsworth, of Jefferson City, Tenn., October 5.

Edgar Hall Hand, M.D., to Miss Nannie Williamson, both of Pineville, N. C., in Charlotte, N. C., September 22.

T. Flournoy Worthington, M.D., Myrtle Grove, La., to Miss Celeste Scudder, of Vicksburg, Miss., September 22.

Edgar Clyde Jones, Medical Reserve Corps, U. S. Army, to Miss Anne Katherine Laughlin, of Silver City, N. M., September 16.

Henry Arthur Cassebeer, Jr., M.D., to Mrs. Eleanor Genevieve Pacake, both of New York City, in London, England, September 29.

Deaths

Harry Dorr Niles, M.D. Medical College of Ohio, Cincinnati, 1880; a member of the American Medical Association; in 1907, president of the Utah Medical Society; formerly president of the Western Surgical and Gynecological and Rocky Mountain Inter-State Medical associations; chief-of-staff of the Holy Cross Hospital, Salt Lake City; Utah; an honorary member of the state associations of Colorado and Idaho; died at his home in Salt Lake City, September 28, from cerebral hemorrhage, aged 53. The Salt Lake Medical Society, Salt Lake County Medical Society, and medical staff of the Holy Cross Hospital, at special meetings, adopted resolutions of regret and condolence.

George Edward Post, M.D. New York University, New York City, 1850; dean of the faculty of the Syrian Protestant College, Beyrout, Syria, Asia Minor; professor of surgery in the Syrian Protestant Hospital; and surgeon of the Johanniret Hospital, Beyrout; whose work in the medical missionary field won for him the decoration of the Osmanieh from the Sultan of Turkey, and of the Red Eagle and Knights of Jerusalem from Germany; author of text-books on botany, zoology, physiology, surgery, and materia medica, primarily for the use of his students; died in Beyrout, September 30, aged 70.

Christopher James Cleborne, M.D. University of Pennsylvania, Philadelphia, 1860; rear admiral U. S. Navy, retired; who entered the Navy in May, 1861, served through the Civil War, and during the Spanish-American War was in command of the U. S. Naval Hospital, Norfolk, Va.; served on sea duty for ten years and eight months, and on shore duty for twenty-five years and five months; was retired November 10, 1899 for incapacity resulting from incident of service; died at his home in Washington, D. C., October 2, aged 71.

Pasquale DeCunto, M.D. University of Naples, Italy, 1898; a member of the Colorado State Medical Society; a prominent Italian physician of Denver; who on account of his work in behalf of his fellow-countrymen was made a chevalier of the Order of the Crown of Italy by the King; died at the home of his mother-in-law in Brooklyn, N. Y., October 6, from bronchitis, aged 43.

John Joseph Quirk, M.D. Rush Medical College, Chicago, 1888; a member of the American Medical Association; adjunct professor of skin and venereal diseases in the College of Physicians and Surgeons, Chicago, and the Chicago Clinical School, secretary of the local board of U. S. Pension Examining Surgeons; died at his home in Chicago, October 4, aged 44.

John Newton Gregg, M.D. University of Michigan, Ann Arbor, 1862; of Whittaker, Mich.; professor of anatomy in his alma mater from 1862 to 1864; surgeon of the Twenty-fifth Volunteer Infantry during the Civil War; died at the home of his nephew in Fond du Lac, Wis., September 28, from heart disease, aged 73.

Daniel A. Smith, M.D. Eclectic Medical Institute, Cincinnati, 1855; surgeon of the Twenty-second Georgia Infantry, C. S. A., during the Civil War; mayor of Butler, Ga., and afterward state senator; later mayor of Anthony, Fla., and a member of the legislature; died recently at his home in Anthony, aged 79.

Henry A. Eidson, M.D. Rush Medical College, Chicago, 1880; a member of the Illinois State Medical Society; and of the local board of U. S. pension examining surgeons; died suddenly, while making a professional call at his home in Willow Hill, October 7, from hemorrhage, aged 62.

Charles Horace Evans, M.D. Homeopathic Medical College of Pennsylvania, Philadelphia, 1869; of Chicago; from 1897 to 1904, lecturer on materia medica in Hahnemann Medical College; died in Union Hospital, Chicago, October 4, after an operation for carcinoma of the stomach, aged 62.

Harold Verne Noyes, M.D. Medical School of Maine, Brunswick, 1881; a member of the York County (Maine) Medical Society; for many years superintendent of schools of Berwick; died at his home in Berwick, January 25, from cirrhosis of the liver, aged 50.

Charles Alonzo Cordiner, M.D. Baltimore (Md.) Medical College, 1901; of Portland, Ore.; formerly of Astoria, Ore., and secretary of the Clatsop County Medical Society; died in the Good Samaritan Hospital, Portland, September 25, from spinal meningitis, aged 29.

James Fulton, M.D. Jefferson Medical College, Philadelphia, 1859; a member of the Medical Society of the State of Pennsylvania; one of the oldest practitioners of Chester county; died at his home in New London, September 28, from angina pectoris, aged 77.

Edward Pierson Nicholson, M.D. University of Nashville, Tenn., 1861; a member of the Medical Association of the State of Alabama; died at his home in Valley Head, September 29, from the effects of aconite, taken by mistake for cough syrup, aged 74.

Ludwig Kohn, M.D. University of Vienna, Austria, 1887; a member of the Medical Society of the State of New York; died at his home in New York City, October 4, from the effects of carbolic acid, taken in mistake for a nerve tonic, aged 45.

Charles Parsons Beaman, M.D. New York Homeopathic Medical College, New York City, 1882; a member of the American Medical Association; physician to Cornell University Athletic Association, Ithaca, N. Y.; died October 6, aged 49.

Junius Kincaide Battle, M.D. Tulane University, New Orleans, 1883; a member of the Medical Association of the State of Alabama; city physician of Eufala, Ala.; died at his home in that city, September 28, from cerebral hemorrhage, aged 48.

Otto Frankenberg, M.D. Starling Medical College, Columbus, Ohio, 1870; for twenty years a member of the faculty of his alma mater; died at his home in Grand View, Columbus, September 29, from disease of the bladder, aged 63.

Julian Branch, M.D. Detroit (Mich.) College of Medicine, 1905; of Otisville, Mich.; a member of the Michigan State Medical Society; died in Harper Hospital, Detroit, after an operation for appendicitis, September 30, aged 32.

Charles Frederick Ferguson, M.D. Queen's University, Kingston, Ont., 1859; formerly member of Parliament for Leeds and Grenville, Ont.; died suddenly at his home in Kemptville, Ont., October 1, aged 76.

Riley S. Lycan, M.D. Homeopathic Hospital College, Cleveland, Ohio, 1880; a member of the Illinois State Medical Society; died at his home in Paris, October 2, from pulmonary tuberculosis, aged 54.

Russell Clute, M.D. Albany (N. Y.) Medical College, 1903; of Maplewood, N. J.; physician to Christ's Hospital, Jersey City; died at the home of his sister in Amsterdam, N. Y., September 24, aged 33.

William Alexander Brooks, M.D. Jefferson Medical College, Philadelphia, 1850; a retired practitioner of San Antonio, Texas; died at a local sanitarium, September 18, from senile debility, aged 84.

Ernest Clark Gwinn, M.D. College of Physicians and Surgeons, Chicago, 1906; formerly of Sadorus and Paris, Ill.; died in Monrovia, Cal., from pulmonary tuberculosis, September 9, aged 28.

Joseph S. Biggart (license, Tenn., 1889); an eclectic practitioner of Carroll county, Tenn.; died at his home near Carter's Chapel, recently, and was buried September 26, aged 63.

Isaac M. Mulholland (license, Ohio, years of practice, 1896); for sixty-two years an eclectic practitioner; died at his home in Toledo, June 21, from edema of the lungs, aged 85.

H. F. McCoy, M.D. Columbus (Ohio) Medical College, 1879; formerly of Chauncey, Ohio; died at his home in Harper, Kan., from disease of the kidney recently, and was buried October 3.

William Turner Nolen, M.D. Hospital College of Medicine, Louisville, Ky., 1890; a member of the New Mexico Medical Society; died at Los Tanos, July 14, from tetanus, aged 40.

William A. Childress, M.D. Medical College of Georgia, Augusta, 1858; a Confederate veteran; and a pioneer citizen of Atlanta, Ga.; died at his home, October 1, aged 73.

James Lawson Davis, M.D. University of Alabama, Mobile, 1874; postmaster of Lafayette, Ala.; died at his home, September 12, from strangulated ventral hernia, aged 63.

Jabez Parkhurst Bidwell, M.D. Albany (N. Y.) Medical College, 1860; died at his home in Morrisonville, N. Y., March 17, 1908, after an illness of twelve years, aged 71.

Edmond B. Towne (license, practitioner, Iowa, 1887); since 1876 a practitioner of Coon Rapids, Iowa; died at the home of his son in that city, September 9, aged 80.

John Campbell Buell, M.D. University of Michigan, Homeopathic College, Ann Arbor, 1892; died at his home in Rives Junction, Mich., September 25, aged 39.

Albert Thibodeau, M.D. Laval University, Montreal, 1881; of Escanaba, Mich.; died in the Delta County Hospital, February 13, from carcinoma, aged 49.

Lewis E. Powell, M.D. Atlanta College of Physicians and Surgeons, 1899; died at his home in Waynesboro, Ga.; September 26, from heart disease.

George Harold Grigsby, M.D. University of Louisville (Ky.), 1909; died at his home in West Baden, Ind., September 11, from typhoid fever, aged 26.

Henry B. C. Harris, M.D. New York University, New York City, 1848; died at his home near Wallace, Mo., May 1, from senile debility, aged 83.

Isaac W. Lewis, M.D. Castleton (Vt.) Medical College, 1848; died at his home in Apalachian, N. Y., September 19, aged 88.

Lute B. Irwin, M.D. University of Louisville, Ky., 1858; died at his home in Savannah, Tenn., September 29.

Joseph Francis Xavier Poitras (license, Mass.); died at his home in Brockton, Mass., October 3.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

Dr. McCormack's Meetings Resumed

The public education work carried on by Dr. McCormack was inaugurated this fall with a number of meetings in Kentucky, followed by an address at Marion, Ind., on September 23. The Marion *News-Tribune* says: "The auditorium of the Presbyterian Church . . . was crowded last night with people who appreciated the privilege of hearing Dr. J. N. Mc-

Cormack of Kentucky as well as the fact that his talk did not abound in technical allusions beyond the layman's power of comprehension. The doctor told of what was being done by health boards and physicians generally and referred to the work which remained to be done, but which could not go on without the state's cooperation."

On his way east Dr. McCormack spoke at Greensburg, Pa., on September 25. Extended accounts of the meeting appeared in the local papers. The *Morning Review* says editorially: "His message is one that is clear and truthful and the manner in which he presents it is entertaining and convincing, with good hard facts to back his arguments." The Greensburg *Daily Tribune* says: "An audience entirely satisfactory with regard to size heard the lecture. . . . Fired by intense conviction in all he said, Dr. McCormack made a profound impression as he cited instances of widespread disease and infection resulting from lack of prevention." Dr. James P. Strickler of Scottsdale, secretary of the Westmoreland County Medical Society, writes regarding the meeting: "The society feels that great good has been accomplished. Dr. McCormack's talk in the afternoon to physicians was especially helpful."

The week of September 26 to October 2 was devoted to work in Vermont, meetings being held at Rutland, September 27, Burlington, September 28, St. Albans, September 29, Montpelier, September 30, St. Johnsbury, October 1, and Brattleboro, October 2. The Burlington (Vt.) *Free Press* says, regarding the meeting held at that place: "The address was one of the most interesting and important that has been delivered in this city for a long time." Arrangements have been made for meetings in New Hampshire, North Dakota, Minnesota and Wisconsin during the remaining months of the year.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
Bowling Green, Kentucky

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Second Month—Third Weekly Meeting

DISEASES OF THE BRAIN

Cerebral Hemorrhage

Pathology: Changes occurring in arteries, leading to formation of aneurisms. Hemorrhages may be (a) meningeal, (b) intracerebral, (c) ventricular. Degenerative changes in clot, in gray and white matter.

Intracerebral Hemorrhage (Cerebral Apoplexy)

Primary Symptoms: Onset unusually abrupt. Prodromata infrequent. Loss of consciousness, cyanosis, inactive pupils, stertorous breathing, relaxed sphincters, motor loss, conjugate deviation of eyes and head. Development of hemiplegia, sensory disturbances, reflexes, trophic changes. Diagnosis of lesion at (a) cortex, (b) internal capsule, (c) crus, (d) pons, (e) cerebellum.

Secondary Symptoms: Muscular rigidity, contractures, increased reflexes, atrophy, athetosis, arthropathies, characteristic attitude and gait. Course of disease and prognosis.

Cerebral Embolism and Thrombosis (Cerebral Softening)

Embolism: Etiology, sex, age, endocarditis, atheroma of aorta, in puerperium.

Thrombosis: Etiology, age, sex, infections, cerebral embolism, arteritis and aneurisms.

Symptoms of Cerebral Softening: Onset sudden (embolism) or gradual (thrombosis). Symptoms due to blocking (a) of vertebral or basilar artery, (b) posterior cerebral, (c) internal carotid, (d) middle cerebral, (e) anterior cerebral. Differential diagnosis in cerebral hemorrhage and thrombosis.

Society Proceedings

COMING MEETINGS

Amer. Association of Railway Surgeons, Chicago, October 20-22.
American Public Health Association, Richmond, Va., October 19-22.
Hawaiian Territorial Medical Society, Honolulu, November 19.
Kentucky State Medical Association, Louisville, October 19-21.
Medical Association of the Southwest, San Antonio, Tex., Nov. 9-11.
Nevada State Medical Association, Goldfield, November 2.
Southern Medical Association, New Orleans, November 9-11.

INDIANA STATE MEDICAL ASSOCIATION

Sixtieth Annual Session, held at Terre Haute, Oct. 7-8, 1909

The President, Dr. George D. Kahlo, French Lick, in the Chair

Officers Elected

The following officers were elected for the ensuing year: President, Dr. T. C. Kennedy, Shelbyville; first vice-president, Dr. E. M. Van Buskirk, Fort Wayne; second vice-president, Dr. Eugene Hawkins, Green Castle; third vice-president, Dr. Theodore Potter, Indianapolis; secretary, Dr. F. C. Heath, Indianapolis; treasurer, Dr. David W. Stevenson, Richmond; delegates to American Medical Association, Dr. A. C. Kimberlin, Indianapolis, and Dr. C. H. McCully, Logansport; alternates, Dr. Fred A. Tucker, Noblesville, and Dr. J. Rilus Eastman, Indianapolis.

Fort Wayne was selected as the place for holding the next annual meeting.

Defense of Malpractice Suits

A committee of three was appointed for the purpose of thoroughly considering and investigating from a legal standpoint if it is feasible to establish a fund for the purpose of defending malpractice suits.

Pure Food and Drug Legislation

The following preambles and resolutions were adopted:

Whereas, The Indiana State Medical Association recognizes the great work that is being done in protecting the health of the *people and preventi* [illegible] *f foods and drugs by* the enforcement of [illegible]; and

Whereas, It is [illegible] inufacturing interests are endeavoring to [illegible] and to harass and hinder the officials i [illegible] law; therefore, be it

Resolved: That tl [illegible] Association expresses its confidence in the Indiana State Board of Health to resist any effort made by manufacturers or others, which may in any way weaken the efficiency of the pure food and drug law, or restrict the scope of its operation; and be it

Resolved: That the Indiana State Medical Association does not accept the decision of the Referee Board appointed by ex-President Roosevelt as final, and that it recommends to the President of the United State and the Secretary of Agriculture that further investigations conducted on the broadest lines be continued, that the people and the food producer may know the value, the necessity or harmfulness of any or all food preservatives; and, be it further

Resolved: That the Indiana State Medical Association recognizes and emphatically endorses the work of its fellow-citizen, Dr. Harvey W. Wiley, in his untiring efforts extending over many years to obtain for the people pure foods and pure food legislation, and that it expresses its appreciation of his work by sending him a copy of these resolutions.

Estivoautumnal Malaria

Dr. G. D. Marshall, Kokomo: Seventy-five per cent. of the applications for pensions made by the Spanish-American War veterans were for disabilities due to malarial infections received while in the service, diarrhea and gastrointestinal troubles with nervous breakdown being the alleged causes of disability, which really was a chronic malarial manifestation. I have examined a number of these men and found plasmodia in the blood and obtained a history of recurring attacks once or twice a year ever since the original infection was received while in the service. The burden of diagnosis in these cases rests on a microscopic examination of sputum and blood and the value of these is a matter of individual skill and sincerity. If one has not the technical skill to make the microscopic examination, the chances are that blood films will be so poorly made that examination by an expert would be very unsatisfactory. Quinin is a specific for this disease and will give relief from the symptoms in less time than any other drug if given in sufficient dosage and in a form in which it is absorbed. From 10 to 80 grains should be given daily in combination with an acid to render it soluble. There is usually a severe reaction in the chronic patient who has not received antimalarial treatment. The rapid destruction of the parasites and the breaking down of the corpuscles that contain them cause the formation of enormous quantities of bile, and bilious vomiting is very likely to follow unless the bowels are moved freely. Calomel and phenolphthalein serve this purpose. Iron and quinin should be given for the color test, for hemoglobin may show from 80 to 100 per cent., but this does not signify that the cells are rich with hemoglobin, as there are so many crippled cells that the available oxygen-carrying power of the blood is diminished, giving rise to shortness of breath. Quinin tablets are so insoluble that they should not be depended on. Treatment should be continued for months, especially in severe chronic cases. Recurrent and primary attacks are much easier controlled. I do not make any restrictions in diet, but encourage the patient to take nourishing food whenever the stomach will tolerate it. Cupping or the local application of solidified liniment in which camphor and menthol are incorporated gives relief from the pains due to the neuritis.

DISCUSSION

DR. W. T. S. DODDS, Indianapolis: It is impossible to find the malarial parasites in the peripheral circulation in the estivoautumnal cases after any considerable length of time with any decided determination. From observations which I have been able to make, dating back to 1898, the time when the soldiers returned from the south, as well as the observations of Craig, of the Public Health and Marine-Hospital Service, on the Pacific Coast, I am led to believe that one dose of quinin will drive the parasites from the peripheral circulation, so that they would not be found once in a thousand cells thereafter, unless puncture of the spleen is made. The difficulty of diagnosing malaria from the blood, especially stained blood, is very great. It is particularly difficult in the dry specimen and it requires several examinations before one can prove or disapprove malarial fever, particularly of the estivoautumnal variety. Perfectly normal blood will give one observations which are distinctly disturbing, and repeated examinations are required. While Wright's stain for blood is admirable, at the same time it does not fulfill all the requirements of a blood stain. As to the question of the breeding of mosquitoes in malaria, there is no doubt about that, but there seems to be some question with regard to previous infection. All cases of chills and fever accompanied with gastrointestinal disturbances are not malaria by any means, even if the fever disappears under quinin. A fever which does not respond to large doses of quinin in two or three days is not malarial.

DR. SIMONS, Indianapolis: I agree regarding the difficulty of diagnosing malaria with the stained specimen. Fresh blood, when it can be properly obtained, is much more reliable and much more satisfactory to the man who is making the examination than a stained specimen. One who has examined a great many smears can acquire a degree of aptitude in that kind of work, so as to be able to recognize the parasites without any great degree of error. One should get acquainted with the stain. The form of the organism and the manner in which the blood was taken have a great deal to do with the difficulty. This summer, at the state laboratory, we had seventeen samples of blood that showed the malarial parasite, but only two could be diagnosed as estivoautumnal. Only two showed the crescent form and both of these patients came from outside of the state; one from Arkansas and the other from St. Louis. About twelve out of the seventeen obtained their infection, according to the statements of their physicians, in the state of Indiana, and most of them came from along the Wabash River. For some reason or other there seems to be an increase in the amount of malaria that has occurred in Indiana during the past summer and just why that is I hardly know.

DR. HUGO O. PANTZER, Indianapolis: It takes a courageous spirit nowadays to assert that malaria is still prevalent to any great extent in Indiana. I have found malaria all these years and have contended for its presence and have encountered denial and ridicule. I wish to speak in support more particularly of cases of malaria that are distinctly of the estivoautumnal type. When the malarial parasites are in possession of an individual, they are commonly entrenched with him. I mean by this that when the malarial plasmodium of the estivoautumnal type is once entrenched in the ordinary case, they will continue through life. The estivoautumnal type of fever is present with us almost all the time in those individuals who had it in their youth.

DR. B. W. RHAMY, Fort Wayne: The only cases of malaria, with the exception of one, that I have found have come from out of the state; as, for instance, from Missouri and Mississippi or from the Spanish-American War.

DR. G. D. MARSHALL, Kokomo: The Wright stain is recommended by all authorities that I have read on blood examinations for staining purposes in cases of malaria. As to finding the parasites in the peripheral circulation, they are expected to be found there. I do not recall having read any authority on this subject who would hazard the puncturing of the spleen to obtain blood, as it is too dangerous an operation and is so considered by men who have written on the subject. I believe the parasites can be found in the peripheral blood.

Value of the Leucocyte Count

DR. B. W. RHAMY, Fort Wayne: A differential count is of much more value than a total count. The differential and total count, taken together, may, and often do, give much valuable diagnostic and prognostic aid. The differential count gives an index of the amount of toxic absorption. A high neutrophile count, with a high total count, indicates either an acute systemic infection, a gangrenous process, or suppuration. A neutrophile count above 80 per cent. usually means suppuration. A low polynuclear or total count, in the presence of a severe process, denotes low resistance, proportionate to the decrease. An increase of large lymphocytes, accompanied by an eosinophilia, is presumptive evidence of syphilis in a suspected case. An increase of large lymphocytes and transitional cells, with a diminution of neutrophiles, small lymphocytes and eosinophiles, in the presence of a continued fever, is strong evidence in favor of typhoid. Leucocytic crises may occur in typhoid. Typhoid usually has a leucopenia during the first week; after the first week, leucocytosis is common. A small lymphocytosis may be part of the early pathological changes in thyroidism. The rôle of the transitional cells seems to favor the theory that the large mononuclear cell is the common origin of all forms of leucocytes.

DISCUSSION

DR. H. R. ALBURGER, Bloomington: I wish to call attention to the fact that the average physician must depend on the laboratory worker to make these compilations and do this work for him. In the first place, in making a blood count I find in my laboratory work that a great many practicing physicians, skilful men, do not realize that blood counting cannot be done in a laboratory one hundred miles away from the case. It requires technical skill and rapid careful technical work to make a good blood count, and the physician who intends to follow up his cases to the ultimate clinical analysis should familiarize himself with the technic for making blood counts.

DR. H. H. THOMPSON, Noblesville: Those of us who make our own smears are apt to find the blood at one end of the slide thicker than the blood at the other end of the slide, and I wish to emphasize this fact in the differential count, and how much it means to any one that will take the least time and trouble to look into the matter. Lymphocytes in excess are an indication of resistance. They are an indicator of whether or not the body will be able to survive the infection. When we go into the matter of the differential count we are able to make a better prognosis in the disease with which we have to deal.

DR. A. C. KIMBERLIN, Indianapolis: The numerical count is not reliable unless one is able to estimate correctly the amount of resistance or vital force of the patient himself.

DR. B. W. RHAMY, Fort Wayne: Ordinarily a specimen is sent to the laboratory with the request for a blood examination and report. The laboratory man should have at all times a history of the case and be enabled to confer with the clinician with regard to his findings and the clinical findings in order to do good and satisfactory work.

The Treatment of Pulmonary Hemorrhage

Dr. Theodore Potter, Indianapolis: The first and most important thing to secure in the presence of pulmonary, as of other hemorrhages, is rest and quietude of body and mind. The patient, except in the unusual cases of profuse bleeding from a ruptured large vessel or aneurism, may be assured that there is little danger; that the loss of a few ounces or a pint of blood will of itself do little harm and may be beneficial in relieving congestion. Thus the fright may be allayed and nervous excitement lessened. If the bleeding may be in any degree profuse, or be continuous or recurrent, absolute bodily quietude should be enjoined. What are the other things which may help to arrest bleeding? They lie chiefly in four directions: to lower the blood pressure in the lungs; to divert the blood from the lungs on the principle of revulsion, to immobilize the bleeding lung as far as practicable, and to use such artificial measures as are safe to promote the general and local quietude. The last indication is best met by opium.

DISCUSSION

Dr. G. T. McCoy, Columbus: Some hospitals report as high as 10 per cent. of fatal cases of tuberculosis terminating by hemorrhage, and others as low as 1 per cent. of fatal cases. One cannot always determine the location of the hemorrhage, and the condition of the patient forbids anything but a very slight examination, confined to auscultation only for fear of adding to the seriousness of the case. Hemorrhage may be the first indication that any lesion of the lungs exists, but it does not in any manner indicate the extent or duration of the disease. It may come from a tuberculous infiltration of the vessel wall, or a destruction of tissue immediately surrounding the vessel and be the only part of the lung diseased. When it is the first manifestation of a lung lesion a serious hemorrhage need not be expected. When called to a case of pulmonary hemorrhage the physician should at once attempt to gain the confidence of the patient, allay his fears, and obtain quiet not only of the patient but of his surroundings. Quiet of mind and body is essential. The lowering of the blood pressure is of prime importance. This I generally secure by the administration of nitroglycerin in 1/100 grain tablets, dissolved on the tongue, or one minim of a 1 per cent. solution of nitroglycerin administered hypodermically. I follow this with veratrum viride until a marked impression is made on the pulse and seek to maintain this condition for several hours. If there is evidence of collapse, this treatment is not indicated. I seldom recommend opiates.

Dr. Joseph Collins, New York City: It has been my practice in hospital work, where I see a large number of cases of tuberculosis, to do nothing in the treatment of hemorrhage from the lungs save to give a dose of nitroglycerin, and if there is any considerable stress of mind or body in the shape of cough or physical agitation to combine the nitroglycerin with small doses of morphin. In the practice of internal medicine ergot has done more harm than good. In the past it has been used as a remedy for almost every spinal cord disease, and I hope it will be abolished except for use in bringing about contraction of the uterus.

Dr. F. B. Wynn, Indianapolis: I believe that generally we can tell where hemorrhage comes from in these cases. In the first place, the type of hemorrhage may be noted often times in the sputum in which the masses are simply tinted, pin-head sized or larger masses of blood than the mucus. Such minute hemorrhages may come and generally do come from the bronchial tubes; that is to say, in conjunction with any pulmonary condition in which there is a paroxysm of coughing, with prolonged effort and inducing passive congestion of the mucosa of the bronchial tubes, tiny capillaries may rupture and minute hemorrhages of this character occur. These paroxysms occur when there is associated laryngeal tuberculosis, with prolonged whooping cough-like paroxysms. The hemorrhage the essayist discussed is a hemorrhage *en masse*, and such hemorrhages must come when there is destruction of lung tissue. These big hemorrhages generally mean abscess or necrosis of lung tissue. In the treatment quiet and rest are very essential. This can be induced by morphin and other measures.

Dr. T. Potter, Indianapolis: I should have said something about the use of the nitrates in my paper, as they seem to be coming into use more of late than formerly. A great many practitioners speak of them in reducing blood-pressure, and they are especially noted for their quick action; yet from my experience, where there are no contraindications to their use, I am inclined to believe that such drugs as aconite and veratrum are valuable.

AMERICAN ROENTGEN RAY SOCIETY

Tenth Annual Meeting, held in Atlantic City, N. J., Sept. 23-25, 1909

The President, Dr. George C. Johnston, Pittsburg, Pa., in the Chair

Officers Elected

The following officers were elected for the ensuing year: President, Dr. George E. Pfahler, Philadelphia; vice-presidents, Drs. Vernon J. Willey, Rochester, Minn.; C. E. Coon, Syracuse, N. Y.; R. D. Connell, St. Louis, Mo.; and R. D. Hammond, Providence, R. I.; secretary, Dr. Percy Brown, Boston; treasurer, Dr. Charles F. Bowen, Columbus, Ohio.

Detroit was selected for the next place of meeting, time of meeting to be decided later.

Journal to Be Established

It was decided to substitute for the annual volume of transactions a quarterly journal, to be devoted entirely to the use of the Roentgen ray in medicine. The first issue of the journal will appear about December 1. The editor is Dr. P. M. Hickey, Detroit, Mich.

Roentgen-Ray Examination of Mastoid Region

Dr. Sidney Lange, Cincinnati, Ohio: A skiagraphic examination of the mastoid region is very valuable as a means of diagnosis in mastoid disease. The skiagraph is made with the patient lying on the side, the rays being projected from above and behind, and pointing toward the mastoid of the opposite side. An exposure of from five to ten seconds is made, both sides being skiagraphed for purposes of comparison. The most reliable results were obtained in chronic cases, the skiagram usually showing more or less marked sclerosis with haziness or obliteration of the mastoid cells. In several instances the skiagraphic diagnosis was confirmed by operation. Only a small number of acute cases were examined, and no conclusions could be drawn. Severe acute cases, accompanied by extensive bone destruction, were easily recognized. In two cases, abscess of the mastoid was diagnosed and verified by operation. There must be cooperation between radiographer and otologist for the purpose of comparison and verification of the findings.

DISCUSSION

Dr. Charles F. Bowen, Columbus, Ohio, cited an instance in which a skiagraphic examination would have aided the operator to avoid entering an anomalous lateral sinus during an operation, thus obviating a second operation.

Dr. W. F. Manges, Philadelphia, pointed out the advantage of stereoscopic radiography in this connection, and exhibited skiagraphs of a number of cases.

Relations Between Bodily Deformity and Gastrointestinal Irregularities

Dr. Percy Brown, Boston: Two classes of cases may be considered under this head: (1) the class in which an apparent postural deformity overtops in importance subjective signs; (2) a class in which gastrointestinal symptoms continue to exist because of failure to recognize the real cause of the trouble. The Roentgen method of diagnosis is applicable in each class. Etiologically, there must be considered (1) accidental deformities, and (2) wilful disfigurement of the body. For instance, in cases of lateral spinal curvature, the stomach may be so outlined as to make it appear almost inconceivable that ordinary peristalsis was not interfered with seriously. in kyphotic asymmetries of the spine, especially of tuberculous origin, no appearances in the shape and position of the stomach was found differing from those in scoliotic cases. It would seem, therefore, that the torsion of the stomach commonly seen in the scoliotic cases has a certain bearing on the malposition of the stomach. Other cases in which alimentary imperfections are often found are those in which occupation postures and other postural habits are the cause of the trouble, but in which the perversion had not become structural. In this class are the milder types of postural lateral spinal curvature, round back, etc. The wilful disfigurements of the body leading to visceral ptoses are the result of tight lacing, etc.

DISCUSSION

Dr. Charles M. Hazen, Richmond, Va., pointed out that in most of these cases there is a lack of tone in the spinal column which he thought had been overlooked as a cause of ptosis.

Roentgen-Ray Diagnosis of Achondroplasia and Cretinism

Dr. Henry K. Pancoast, Philadelphia: I found striking characteristic radiographic features in a case of achondroplasia which I had the opportunity of observing. There was decided deficiency in the epiphyseal development of the shafts of the extremities, making them appear short, both actually and relatively, in comparison with other long bones. They also appeared to be too thick for their length. There is an abrupt expansion of the diaphysis in the neighborhood of the diaphyso-epiphyseal junction, a rather abrupt bowing of the lower end of the femur, and the upper end of the tibia, with a fairly well-developed head of the femur, a poorly developed short, thin neck, and a far better relative development of the trochanter.* The appearance of the hands and feet is also characteristic, the bone being exceedingly cancellous in structure. There was also a tendency to symmetrical osteomatous growths on the long bones of the upper extremities, and a deficient and irregular ossification and growth at the epiphyseal ends of the diaphyses, particularly in the knee joint. Cretinism, on the other hand, does not present any characteristic radiographic features.

DISCUSSION

Dr. Charles Lester Leonard, Philadelphia: I examined a case of cretinism about eight years ago in which I found distinct and separate foci of ossification in the ends of the tibia and the femur. There appeared to be three rings of ossification in the small bones of the hands and feet. This might be a point of differentiation between cretinism and rickets, and cretinism and achondroplasia.

Dr. P. M. Hickey, Detroit: I have found a corresponding lack of development in the bones and in the mental capacity of the patient, so that a patient with the bones of a 5-year-old child also cerebrated like a child of that age.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Fifty-ninth Annual Session, held in Philadelphia, Sept. 27-30, 1909

(Continued from page 1217)

Resolutions Adopted at the Busineess Meeting

CONDEMNATION OF PRESERVATIVES IN FOODS

The following resolutions were unanimously adopted by the Medical Society of the State of Pennsylvania on September 30, having been introduced into the house of delegates two days previously and considered on three separate days:

Whereas, Public opinion has become much aroused over food adulteration; and

Whereas, Diverse opinions have been expressed concerning the use of preservatives in the manufacture of foods; and

Whereas, Certain preservatives make possible the use of foods that have begun to decay; be it therefore

Resolved, That the Medical Society of the State of Pennsylvania, in convention at Philadelphia, declares that it condemns the use as food preservatives of benzoic, boric and salicylic acids and their compounds, and all other similar chemicals, as, in the opinion of this society, such preservatives are unnecessary and are detrimental to the public health; and be it further

Resolved, That this society is opposed to adulteration of food of any kind whatsoever; and be it further

Resolved, That this society indorses the stand taken by the American Medical Association in its fight against food adulteration, and indorses its action in appealing to Congress for immediate amendment of the national Food and Drugs Act; and be it further

Resolved, That this society indorses the stand taken by Dr. Harvey W. Wiley in his campaign for pure food and pure food legislation; and be it further

Resolved, That the society commend the daily newspapers and individuals who have taken a stand against artificial food preservatives and give them added encouragement to continue their fight.

NOSTRUM ADVERTISING

The following resolution was passed:

Whereas, It is the unanimous opinion of the medical profession that the disuse of nostrums and "fake cures" of incurable diseases can be accomplished only by the education of the public against their use; be it

Resolved, That the Medical Society of the State of Pennsylvania highly commend those newspapers and journals who refuse all nostrum advertisements and condemn such so-called remedies in their news columns.

Fourth of July Celebration Condemned

The report of the Committee on Independence Day fatalities contained the following recommendations:

Legal control of the importation, manufacture and sale of explosives used only for purposes of celebration; municipal control of the use of firearms and explosives and of fireworks during the Fourth-of-July season; municipal participation in substitution methods; the organization of societies for both control and substitution purposes; the most complete possible systematic use of tetanus antitoxin and other medical measures in both the prevention and treatment of tetanus and sepsis; the setting apart of a day in all public schools, academies and colleges during the last days of the session before the summer holiday, to make all possible provision against the evil; the allusion to the matter in all churches on the last Sunday preceding Independence Day; the continuance and increase of the agitation in the newspapers; the continuance of the work by this society.

Approval of Board of Public Instruction

The Committee on Scientific Business recommended endorsing the work of the Board of Public Education of the American Medical Association, and the formation of a committee to cooperate in the undertaking.

Venereal Diseases

Dr. Lawrence Litchfield, Pittsburg: It is probable that in this country the percentage of the population infected with venereal diseases does not vary greatly from that in Germany, where on any single day about 100,000 people are under treatment. The state or municipality has the same moral obligation and the same financial interest in the control of venereal diseases as in the control of any other contagious disease. Any attempt at police control of prostitution without the European system of registration would be futile and impracticable for our American cities. This may not be a misfortune for it is not yet demonstrated that better results cannot be obtained by social organization against the social evil. All who have given much thought to the subject agree that the only efficient method consists in the education of the public, the establishment of free dispensaries for the treatment of venereal diseases with every possible inducement to get the infected to accept the treatment thus offered, the repeal of bad laws and the adoption of new ones which work only for the desired end. I urge the organization, from our present local societies, of an American association for the prevention of social diseases, with branches and dispensaries in all our cities.

DISCUSSION

Dr. Ella N. Ritter, Williamsport: This subject is one of the last that we as physicians have earnestly considered. Eighty per cent. of children are born blind and a large number are stillborn from this disease. Education is the specific at our hand and we should make a better attempt than in the past to do something along this line.

Dr. S. Nelson Wiley, Norristown: I have it on the authority of one of the greatest gynecologists in this city that the great mass of gynecologic abdominal work is due to gonorrhea. If we know that a man is not fit to marry a pure girl it is our business to say so. For a number of years, in the few cases I do treat, I have made it a point to say to the patient that he must not marry until he has the very best evidence of cure. Some of them say: "I will marry when I please." "No," I say, "you will not." The preacher, when performing the ceremony, asks if any one knows any reason why the marriage should not take place. I have a threat standing over four men to-day that I will stand up in any house or any church and say that they are not fit to marry.

Dr. A. E. Roussel, Philadelphia: After a rather extensive observation of the methods employed abroad, more particularly in Paris, in the registration of cases of venereal diseases, I can not but believe that those methods possess advantages over the ones in this country. I hope the time is not far distant when cases of this kind will be required by law to be reported, and I am persuaded that such requirement will aid greatly in the suppression and diminution of this terrible infection. I take it that on the man about town, or the younger man, the possibility of having his name noted on the books of the board of health, would have a very deterrent effect.

Dr. C. L. Stevens: Do I understand that Dr. Roussel favors police regulation of prostitution in this country?

Dr. Roussel: I do.

Dr. Stevens: Would you limit that to the female prostitute, or would you include the male prostitute?

Dr. Roussel: I think the first step in this direction will be on the side of the weaker sex; ultimately I should be in favor of the registration of both sexes.

Dr. Stevens: Have you the statistics in this country where police supervision has been attempted?

Dr. Roussel: I will not say of this city, but I fail to imagine that conditions are so different that the results obtained abroad should not be obtained here.

Dr. Lowell M. Gates, Scranton: I imagine that if the method suggested by Dr. Roussel were carried out it would drive these people for treatment to the illegitimate practitioner, who would shield them from report. In the matter of education I believe we should make the symptoms and consequences of this disease so plain that every woman would know the cause of her trouble in less than a month after marriage, and be in a position to charge her husband as the cause of the infection. For fear of causing trouble we have been too timid in advancing facts. In addition to this we should be willing to stand up and threaten these men. Let us protect humanity!

SYMPOSIUM: THE PROBLEM OF THE PUBLIC SCHOOL FROM THE MEDICAL POINT OF VIEW

The Studies and Their Effects on the Nervous System

Dr. Lawton M. Hartman, York: 1. The subject of nervous diseases among the school children has not received sufficient attention. 2. There is now no definite knowledge of the part played by any particular study or group of studies or any school occupation in the development of nervous affections among school children. 3. There is a large and varied group of nervous manifestations occurring among school children, the development and continuation of which alterations from the normal are attributed to school work and especially to school overwork. 4. Before the age of puberty overwork at school is not a large factor. 5. After the age of puberty, especially among girls, in schools where strong efforts to excel are expended, overwork at school plays a much more definite part. 6. The importance of medical inspection of schools is becoming universally recognized. 7. Broader legislation should be urged for more accurate and more powerful medical inspection. 8. The introduction into the higher educational institutions of departments for the study of the child as an entity has and will produce results most practical, valuable and interesting. 9. The earlier recognition of variations from the normal existing among school children with the institution of medical and educational treatment would accomplish much. 10. The individual management of those pupils nervously affected is the only rational way of providing for the proper and continued education and supervision of the health of the school youth.

School Houses and School Habits and the Development of the Body

Dr. Thomas Grier Simonton, Pittsburg: Physical culture in the school should be taught so that it will become the habit of adult life. Posture, study habit, and concentration are affected by physical culture and correct breathing. The best results are to be obtained by promoting the action of the lungs and digestion and the function of the skin. A foot tub, or wash basin with warm or cold water, soap and a rough towel are procurable in nearly every home, and the pupils should be taught that a daily sponge bath, followed by friction of the skin with a towel, is what is required of them at home, while deep breathing and physical culture is taught them at school. Warden Lewis of the Allegheny county jail at Pittsburg recently inaugurated daily open-air physical exercise for his 800 prisoners. Asked what has been the result, he replied, "better discipline, better digestion, more contentment, less medicine." The best results are obtained only when the physical instructors of the children are living examples of the system employed. Catch-penny stores near schools, with their cheap cakes and candy, their obscene postal cards and literature, are grave dangers. Statistics show the relative ratio between cigarette users and non-users in standing, truancy and juvenile court subjects.

Medical Oversight

Dr. H. Herbert Herbst, Allentown: The paper is a treatise on medical oversight of the public schools, not so much a detail and description of the method itself, but a plea for more interest and a larger introduction of this work into the public schools of this country. The latest reports show the growing sentiment in favor of this work, its importance, and its appreciation by the general public. The measure is not, however, growing throughout the United States in proportion with the amount of good that has been accomplished.

The Knowledge of Most Value to School Children

Dr. George W. Wagoner, Johnstown: The common school system of education is the most important element in the nation's life, providing the only education the vast majority can hope for. Ten years is the limit of time most children have to devote to school. Advanced education and college training can be enjoyed by only a very few. In considering the knowledge which is most valuable, the first and most essential is a thorough knowledge of the alphabet. There are few who leave school and enter on the active duties of life with a working knowledge of the possibilities, the flexibility, and the limitations of the alphabet as a whole, or the correct sounds of its individual elements. The next essential elementary knowledge is spelling. The next is reading—the ability to read with the spoken voice in a clear, distinct and orderly manner so as to convey to the listener the full meaning and beauty of the printed page. Writing is the fourth essential. Arithmetic, the art of reckoning, is another of the elementary essentials of all knowledge. By its principles we reckon the relations between all material objects, we define space, and comprehend time. The development of these units with the subsequent addition of the dependent units, history, grammar, literature, civics, and geography gives a coherent fund of knowledge which is called elementary education. Such education the child has the right to receive from the state. If each pupil is well-grounded in all these branches he has what democratic society undertakes to give him, the essential elements of all human culture, and with them the door is opened and he is at the threshhold of every department of human activity.

Discussion on the Public School Problem

Dr. Charles P. Stahr, Lancaster: Medical men can do much toward furthering the work of medical inspection in schools, and it is to them that the children of the state must look for benefit in physical, mental and medical ways. I believe that chorea among school children is attributable to an inherited, unstable nervous temperament coupled with the desire to outrank other children rather than to the school curriculum. Dr. Hartman's idea of a sort of clearing-house for deficient children coincides with a pet theory of mine. If we had such a psychologic laboratory under the care of persons trained in child study we could help those children who never get beyond the primary grades for five or six years.

DR. EDWARD B. HECKEL, Pittsburg: As has been mentioned, the school boards are absolutely supreme. They fix the tax rate and spend the money as they please, and it is usually spent in putting up very fine buildings which are pointed to with pride as the standard of the education in that community. The public school teacher receives too little compensation. No attraction is offered to young men and young women as teachers. Much of the teaching is faulty and the child, who is an adept in discerning faulty teaching, loses respect for the teaching and the teacher. Especially is this true relative to the evil effects of tobacco and alcohol as taught in the public schools. It would be easy for the teacher to teach that tobacco is always a poison; that though some people stand it very well, others stand it very badly; that it sometimes produces blindness. These are facts which will bear the closest scrutiny.

DR. WALTER S. CORNELL, Philadelphia: The medical inspection of school children rests on three facts: It is important to the teacher because it has a direct relation to the child's education; to the physician, because the health of the child largely determines the health of the adult afterwards; to the state, because the efficiency of the citizens depends largely on their health and physique. In the nervous conditions of school children I agree that the school curriculum is of minor importance compared with other factors. The example of New Jersey should be followed in having a conference between the educational authorities and the medical profession to determine a proper balance.

DR. E. BOSWORTH MCCREADY, Pittsburg: That the medical inspection of schools will soon be universal is the wish of every one with the welfare of humanity at heart. There should also be provision for taking care of the child which may be backward after the physical defect has been remedied.

DR. BATTEN: In the education of our young people we should ascertain to what they are adapted and educate them along those lines.

DR. HAROLD B. WOOD, Philadelphia: Inspection of boarding schools should not be overlooked and physicians should help to patronize those schools in which health conditions are known to be good.

DR. GUMP, Bedford: It is impossible for children at the early age at which they are sent to school, to study as they are expected without being overtaxed. If they were allowed to run wild until 8 years of age before entering a schoolroom, until then being taught by their parents, they would be better mentally and physically.

DR. HEFFNER, Pottstown: In the cities there are all sorts of attractions that affect the children more than study. Not many children are made sick by overstudy. I am the father of six boys, and none of them ever suffered from overstudy, but I must also say that most of those boys were raised in the country.

DR. JOHN C. DEVENNEY, Harrisburg: The dosing of children with "patent medicines," laudanum, and all sorts of anodynes, has much to do with the condition of the eyes. In a case under my observation it was thought when the children started to school that there was a brain condition which prevented them from learning. Correction of the eye defects removed the difficulty.

DR. BROOKS, Wilkes-Barre: We should instruct our house of delegates to confer with the lawmakers on school hygiene, letting it be known that we are desirous of having medical inspection in the cities of Pennsylvania.

Oration on State Medicine: Control of Disease

DR. ARTHUR B. MOULTON, Camp Hill: Frequently the cause of disease is almost within one's grasp and yet the significance of the facts may pass for centuries unnoticed. The idea of segregation is mentioned in the books of Moses. It is presumed that smallpox existed in China more than a thousand years before the Christian era, and scarlet fever nearly 500 years before. No quarantine restrictions were established in England until 1348. The first attempt at the centralization of health authority was made at Venice in 1495. During the first two centuries after this country was discovered no health laws were passed. Probably the first restrictive measures adopted by any central health authority on the American continent was the order issued by court in Massachusetts during 1647. In 1700, a quarantine law was passed in Massachusetts and also in Pennsylvania. All regulations enforced for the control of communicable diseases during the past can be classed under three heads: (1) that which has to do with commercial interests as prompted by the commercial spirit alone; (2) class legislation to protect the rich and cultured from the diseases of the poor, which is purely selfish; (3) the one on which we have entered at the present time for the protection of the people at large.

(To be continued)

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS

Twenty-Second Annual Meeting, held at Fort Wayne, Ind., Sept. 21-23, 1909

(Concluded from page 1220)

Four Hundred and Forty Operations on the Appendix

DR. EDWARD J. ILL, Newark, N. J.: I deplore the late diagnosis and the too-frequent use of the hypodermic syringe, but for these the general results would be much better. Of the 440 patients operated on, 40 per cent. were males and 60 per cent. females. In 81 women the appendix was removed incidentally, while other surgical conditions prevailed and many were shown to be normal by the pathologist. I deplore the frequency with which the appendix is removed, simply because the abdomen is opened, and believe that no operation should be done except for the express purpose of removing symptoms of disease for which the patient seeks advice. Any prolongation of the operation may add to the patient's danger and certainly to his discomfort during convalescence. The youngest person operated on was 5 years old, and the oldest was 65 years. In 43 per cent. of the cases there was suppuration. Among the 189 septic cases there was localized abscess in 109, and diffuse suppurative peritonitis in 70. What seems to be a general peritonitis is recorded in 8 cases, and 2 patients had septicemia. The total number of deaths was 32, or 7.2 per cent. Increased experience shows a marked reduction in the death rate. Thus, in the first 100, it was 18 per cent.; the second 100, it was 6 per cent; in the third 100, it was 5 per cent., and in the fourth 100, it was 3 per cent. The total number of deaths in the non-suppurating cases was 2, to 0.8 per cent. The percentage of deaths in the suppurating cases was 14.3 per cent. Late and hopeless cases accounted for this high death rate. An interesting fact in the death rate was the personal one in the after-treatment. Thus, in 198 patients who were looked after personally by me, the death rate was 3.6 per cent., while in 185 patients looked after by the attending physician, the death rate was 10.3 per cent., or nearly three times as great. The death rate in the cases of diffuse suppurative peritonitis was 10 per cent. I have collected from various hospital reports throughout the country 7,833 reports of operations for appendicitis. The death rate in the non-suppurating cases was 3.7 per cent., while the suppurating cases showed a death rate of 26 per cent. I am never obliged to reopen the abdomen for late symptoms or adhesions. I advise the removal of the appendix in all cases if it can be done in a reasonable time, depending on the conditions of the patient. I urge the use of absorbable suture material in all septic cases. I have used most of the technics recommended for the removal of the appendix, but have always returned to the cautery above the ligature and the purse-string suture. I insist that much mischief has been done by not draining septic cases. In these cases I have adopted the right lateral semiprone posture, in such a way that the opening in the abdomen is in the most dependent part of the peritoneal cavity. The drain can be brought out through the upper end of the incision, thus reducing to a minimum the danger of hernia, of which I have seen less than 1 per cent. in my cases, and this also does away with the stab incision in the loin. The position is kept up for twenty-four hours.

A New Point in Diagnosis Between Appendicitis and Tubal Diseases

Dr. Robert T. Morris, New York: Hypersensitiveness at the site of the right group of lumbar ganglia indicates that the appendix alone is the center of irritation. Hypersensitiveness of both right and left groups of lumbar ganglia indicates that some pelvic structure is the center of irritation. In cases in which there is a question if the appendix or some pelvic structure is causing local or reflex disturbance, we can commonly make a differential diagnosis at once by making deep pressure over the sites of both groups of lumbar ganglia, and noting whether these groups, or only the right group, are sensitive to an important degree.

Is the Routine Administration of the Preoperative Purge Defensible?

Dr. Edwin Walker, Evansville, Ind.: Purgatives can do harm and should be given only when the indications are clear. The profession should abandon the slipshod routine methods now in vogue, and should teach the laity, both by precept and example, the evils of the purgative habit. The practice of purging all patients before surgical operations is unnecessary and injurious; they are made more uncomfortable, are weakened, and the condition of the intestinal canal is not rendered more favorable, but, on the contrary, germ activity is stimulated, just as it is in enteritis, thus increasing the probability of infection when the gut is opened, and there is in addition to this more postoperative tympany. A diet of digestible food for twenty-four hours or more and a fast of eight or twelve hours before operation will put the intestine in the best possible condition for any operation, especially on the intestinal canal, except when obstructive lesions exist, and for these purgatives are worse than useless and other measures are required. In a few cases of milder fecal stasis a purgative several days before operation, followed by enemas, is of service. These cases, however, are extremely rare. The routine use of any powerful drug is to be deplored, and the habitual, preoperative purge is indefensible. The continuance of this practice indicates mental stasis of the surgical mind.

Cesarean Section, Abdominal and Vaginal, Compared and Contrasted

Dr. Miles F. Porter, Fort Wayne, Ind.: (1) With a living and viable child the abdominal is the operation of choice. (2) The vaginal operation is probably never indicated in placenta prævia. (3) In cases demanding quick delivery in which the only obstacle is an undiluted os, the vaginal operation should be done. (4) Infection should not decide us in favor of either operation, but the fact that its existence adds to the mortality of both should admonish us that neither is to be regarded an operation of *dernier ressort*. (5) With a dead or dying mother, and a living, viable child, the abdominal operation should be done. (6) Better knowledge of the indications for these operations and a timely resort to them will materially reduce both the maternal and fetal mortality and morbidity. Too little attention is paid to the life of the unborn child and too little to the morbidity of both child and mother. Obstetric procedures should be conducted with a view to perfect the recovery of the mother and the normal development of the child. The term, vaginal Cesarean section, is a misnomer. Owing to the contracted and badly lighted field, obscuration of the field by blood, difficulty of attaining and maintaining perfect asepsis and difficulty of delivering the child, the vaginal operation is the more difficult. The only obstacle to delivery which is removed by the vaginal operation is the cervix. The placenta is avoided by the vaginal operation except in cases of placenta prævia. The wound is nearer the ideal after the abdominal operation. There is greater likelihood of infection after the vaginal operation, but if infection occurs the danger would be greater after the abdominal operation. Patients are more likely to object to the abdominal operation. Previous infection increases the danger of both operations. Remote dangers, such as rupture of the uterus, are about equal and very slight in both operations. Abdominal operation offers the child the best chance, the maternal mortality is about 1.58 per cent. that of the vaginal varies from 0 to 6.5 per cent. The maternal morbidity is less after the abdominal operation.

Methods of Drainage in Abdominal and Pelvic Surgery

Dr. James F. Baldwin, Columbus, Ohio: In this paper I urge the more frequent resort to vaginal drainage in pelvic cases, in which pus is present, or extensive adhesions, and drainage through a stab incision in certain cases of appendicitis. I advise the use of gauze, not so much for real drainage as to keep the intestines from contact with raw or infected surfaces. The use of the word "fluffage" would be more appropriate than "drainage" in these cases for the purposes intended. The gauze is passed through an incision in the vaginal vault from above down, the opening in the vault being of ample size, and the gauze being then so placed as lightly to fill the pelvis. In this way the gauze keeps the intestines out of the pelvis and at the same time absorbs all discharges. The gauze is left in place one week and then withdrawn. Sterile douches are then used until the cavity thus left becomes obliterated. I have used this method for many years, and in a large number of cases, with satisfactory results, both immediate and remote.

How Can We Best Educate Women to Seek Relief Early from Carcinoma of the Uterus?

Dr. C. C. Frederick, Buffalo, N. Y.: The statistics of operations done for carcinoma of the uterus are much better from German clinics than in this country, not because Germany has more skilful operators but because the women are operated on earlier, having been taught to consult the surgeon early when they have symptoms of malignant disease of the uterus. I think there is a belief among general practitioners in this country that hysterectomy for carcinoma of the uterus is an unsuccessful operation, in so far as it prevents recurrence. Such has been the case and will continue to be so long as women so suffering are not operated on earlier than they have been in the past. Early radical operations give good results, and they ought progressively to give better and better results. Hysterectomy for carcinoma of the body of the uterus gives notably better results even in late cases than when the cervix is involved. Women should not only be taught that early operation gives better results, but also that the severity of the operation and the mortality and the morbidity are decreased thereby.

Phlegmasia Alba Dolens

Dr. William A. B. Sellman, Baltimore, reported a case of this nature in connection with an ovarian tumor. He presented photographs showing the size of the tumor, the amount of abdominal distention, and the swollen limb. He considers that the phlegmasia alba dolens in this case was due to pressure on the iliac vessels on the left side, and that this pressure was immediately relieved with removal of the tumor. The patient was fortunate in the rapid restoration of the circulation and in not having had a clot form, which might have destroyed life by the entire clot, or a portion passing to the heart.

Removal of Upper Portion of Rectum and Sigmoid

Dr. Thomas B. Noble, Indianapolis, related the case of a married woman, thirty-three years of age, in whom he extirpated the upper portion of the rectum and sigmoid for cancer. In connection with this case he showed an instrument which will be helpful in this class of cases. It is the result of a study and use of Murphy's button. It has some advantages, he asserted, over the button in this class of work, in that it can be introduced more quickly; it serves as a splint to the soft parts; admits of irrigation of the colon, and the prevention of impaction, and by continuous drainage keeps the bowel quiet, thereby favoring prompt and perfect union. He believes that it is a useful means to the ideal end, namely, an intact abdomen, intact intestine, and competent anal sphincters.

Malignant Tumor of Undescended Testicle

Dr. O. G. Pfaff, Indianapolis: The patient was a man of 38. Examination disclosed a tumor the size of a fetal head, occupying the left lower abdomen and pelvis. The tumor was freely movable within moderate limits, but was apparently attached by a pedicle to a point near the internal inguinal ring. The mass was diagnosed as a malignant tumor of the undescended left testicle, and three days later the man submitted to operation. Through an incision made to the left of the median line, the relationships of the mass were easily made out. The pedicle was attached at the internal ring, and there were some recent adhesions to the bladder, which were easily broken up, the pedicle ligated, and the mass removed. The man made an uneventful recovery from the operation, but within five months died of malignant disease. I did not see him after he left the hospital, and did not learn the location of the later growth, other than that it seemed to affect both the bladder and the bowels. The microscopic examination of the growth showed it to be a large round-celled sarcoma.

Terminal Events in Gall-Stone Disease

DR. CHARLES N. SMITH, Toledo, Ohio: That gall-stone disease is extremely prevalent, afflicting from 7 to 10 per cent. of adults dying in the public hospitals of England, Germany and America, is a contention apparently substantiated by the records of thousands of post-mortem examinations. Rupture of the suppurating gall-bladder into the general peritoneal cavity is by no means an unusual terminal event, having occurred five times in my own experience. Of these five patients, four made a complete recovery after operation, while in the remaining case, a desperate and delayed one, with widespread peritonitis, the patient died on the table as the abdominal incision was completed. From observation of these and other cases, and from a study of the literature, I am convinced that the frequency with which rupture of the gall-bladder occurs as a terminal event in gall-stone disease is scarcely appreciated. These cases are commonly diagnosed as peritoneal infection from appendicitis, operation done on this diagnosis and the case so recorded unless gall-stones, correcting the diagnosis, are found in the peritoneal cavity. One of my patients, a few months before coming to me, had been operated on for a supposed appendicitis and the appendix removed. When a gauze drain was being removed, following the operation, a gall-stone escaped from the cavity and others were expelled at subsequent intervals. Pus was discharging from the incision when the patient consulted me, and several gall-stones were removed from the sinus by the scoop. The gall-bladder, containing one immense stone, and a number of small ones, was removed and recovery followed. Two other patients were brought for operation with a diagnosis of appendicitis, because of pain, tenderness, and swelling in the right half of the abdomen. Correction of the diagnosis prior to operation was not difficult. Free incision, removal of gall-stones, cleansing of the cavity, abundant drainage, with the patient in the Fowler position, were followed by slow but eventful recovery. Of the many terminal events of gall-stone disease, malignancy is without question the most hopeless from the standpoint of cure. That primary malignant disease of the gall-bladder and ducts is preceded by gall-stones in practically every instance, is the experience of surgeons and pathologists. It would seem that a due appreciation of the frequent occurrence and the serious import of these complications must lead to the surgical removal of gall-stones as a conservative and prophylactic measure, long before the opportunity is given for the onset of these terminal events. That this may be done will require a more general recognition of the initial symptoms of gall-stone disease, with diagnosis based thereon, rather than on the symptoms produced by these same terminal events.

DISCUSSION

DR. MILES F. PORTER, Fort Wayne, Ind.: I wish to emphasize the author's statements regarding the relative frequency of the terminal events of gall-stone disease and the consequent importance of operating on patients with gall-stones before these more serious end-results occur. I was interested in Dr. Smith's remarks on posterior gastroenterostomy in cases in which the pylorus is obstructed because of adhesions about it, or the gut below, or because, on the other hand, of adhesions that are hard to break up which hang the pyloric orifice up under the liver. This has occurred a number of times, and in some of the cases the separation of the adhesions has not only been difficult, but accompanied by considerable trauma of the liver, and it is not unattended by danger. In many cases after these adhesions have been liberated there is a still greater difficulty to overcome, namely, their reposition as they were before, and I am therefore impressed with the fact that many of these can be better treated by posterior gastroenterostomy, in so far as the relief of this feature is concerned. I rarely do a cholecystectomy; it seems to me that the gall-bladder should be preserved as long as it is functionating and communicates with the liver.

DR. THOMAS B. NOBLE, Indianapolis: I wish to refer to that condition in which by pericholecystitis we have changes occurring in the stomach due to engorgement by the inflammatory exudate on the pyloric area. In such conditions we will have gastric neuroses, as well as true anatomic disturbances following. Dr. Smith has advised gastroenterostomy in such conditions. I prefer the Finney operation. I do not favor establishing an artificial opening between the intestine and stomach unless every other procedure fails; but the Finney operation maintains the normal route, makes drainage free and perfect, and in the five cases in which I have practiced it I have had satisfactory results.

Phases of Puerperal Sepsis

DR. HUGO O. PANTZER, Indianapolis: The morbidity and mortality attending obstetrics in private homes as contrasted with the results obtained where confinements have occurred in hospitals, should be a convincing argument in favor of the latter practice. The dislike of midwifery by medical men who seek to limit their practice to a specialty, and the displeasure with which the general practitioner attends obstetric cases have deprived this branch of medicine of the growth and efficiency characterizing other branches of medicine. The acme of the present hospital movements will not have been reached until each community has ample hospital provision for its maternity cases. With the public won over to this innovation, it may be hoped that the old-time natural and happy union of obstetrics and gynecology in one specialty, as still generally maintained in old countries, may again become established with us. Without a specialist in obstetrics in most fields, the practitioner in time of need is driven to accept the service of a man no more skilled than himself. The gynecologist, who avowedly has discarded obstetrics, reasonably enough is called on in these emergencies in few cases and then often too late to give effective succor. This unfortunate situation demands relief. Review of recent literature shows that fuller recognition is taken of the differential pathology of parturient patients, and that skepticism of therapy, at times bordering on nihilism, is the dominant note. The routine treatment of various measures, such as curettement, antiseptic douches, etc., is receiving equally wholesale condemnation by some writers. Interesting statistics show conclusively that a let-alone policy is far superior to the indiscriminate medical and surgical practices of a recent past. Serology is not yet of much practical use, and surgery is indicated in comparatively few cases.

SIXTEENTH INTERNATIONAL MEDICAL CONGRESS

Held at Budapest, Hungary, Aug. 29—Sept. 4, 1909

(Concluded from page 1228)

Total Extirpation of the Bladder

PROFESSOR VERHOOGEN and DR. DE GRAEUWE, Brussels, Belgium: Total cystectomy has been followed by a death rate of 31 in 59 cases collected from literature—i.e., a mortality percentage of 53.4. This serious result of surgical intervention does not depend directly on the removal of the bladder, for it is a simple operation. The danger results from the difficulty of ensuing the free escape of the urine coming from the kidneys and of preventing their infection. It is still more difficult because the ureters are generally already distended and the kidneys affected before operation. The methods which have given the most serious results are those in which the ureters have opened on to the skin (30 per cent.) or left free in the wound (13 per cent.). When one or both of the ureters have been carried into the bowel the death rate becomes formidable (66 per cent.), even when precautions have been taken to have a valve at the ureteral orifice, or to exclude the portion of bowel into which the ureters open. The advantages of the two methods can be combined by performing first a double nephrostomy and then a cystectomy with ureterostomy into the excluded cecum. If the ureterostomy works well, the renal fistulas may be allowed to close. Total cystectomy is indicated: (1) malignant tumors of the neck of the bladder or in the neighborhood of the ureteral openings; (2) malignant tumors elsewhere in the bladder too extensive for a partial operation; (3) recurrent malignant growths; (4) papillomata too numerous to be removed in any other way; and (5) involvement of the bladder to a great extent by neighboring malignant growth.

Results of the Treatment of Exstrophy of the Bladder

Dr. É. Ester, Montpellier, France: Among the harmful results caused by exstrophy of the bladder, three are of especial importance; they are incontinence of urine due to the absence of a sphincter, pain, and suppuration resulting from chronic inflammation of the mucous membrane of the bladder exposed as it is to many irritating and infective causes. The best treatment is that which deals with these especially: (1) None of the methods employed gives an entirely satisfactory result; (2) the methods which aim at a plastic restoration of the bladder or the suture of its edges should be abandoned because they do not cure the incontinence of urine; (3) among the many methods of derivation of the course of the urine there are two which give good results, and which prevent incontinence, these are Maydl's method and Soubbotine's method; and (4) the cases reported are not sufficiently numerous to enable a decided opinion to be given as to which is the better. Nevertheless, the following opinions may be expressed: (1) Soubbotine's method protects more thoroughly against ascending infection than does Maydl's method; (2) from the point of view of technic Soubbotine's method, because of its complexity and the length of the treatment is inferior to Maydl's method; and (3) to appreciate the results obtained by these two methods it is necessary to follow up the cases for a number of years, for it might happen that the anal sphincter might be sufficient to retain the urine at first, but later it might allow a certain amount of incontinence.

The Affections of the Urinary Tract by Colon Bacilli

Dr. Thorkild Rovsing, Copenhagen: In most cases the *Bacillus coli* reaches the urinary organs by way of the bloodstream, and the bacilli give rise to a diffuse nephritis, generally slight but occasionally acute. Often the nephritis gets well rapidly and only a bacteria remains. Frequently the bacilli are introduced into the urinary passages by instruments, or they may wander in owing to a paralysis of the sphincter, but this can never occur if the sphincter is efficient. Occasionally infection occurs from the spreading of inflammation from neighboring organs. Since 1897, I have treated 285 cases of *Bacillus coli* infection of the urinary passages. In 180, the disease arose as an acute nephritis or pyelitis in patients who had never been catheterized. Some of the starting points were tonsillitis, cholecystitis, acute enteritis, appendicitis, colitis, cancer of the colon, and typhoid. Clinically, the hematogenous nephritis frequently commenced with febrile symptoms and hematuria. The blood soon disappears from the urine but albuminuria remained, often with pus and casts. Many miliary abscesses may be present in the kidney, and microscopically there can be seen minute centers of inflammation caused by bacillary emboli. Pyelitis and pyelonephritis may be temporary or chronic; when chronic they are chiefly associated with calculous pyelitis. Cystitis is the rarest manifestation of infection by the colon bacillus, for it does not possess the power of attaching the intact mucous membrane of the bladder. In treatment operative interference is never necessary in uncomplicated infection by the *Bacillus coli*, but if complications are present which hinder recovery operation may be necessary; for instance, if calculi and stricture of the ureter are present. The rational treatment of uncomplicated *Bacillus coli* infection is by flushing out the urinary passages by a free stream of fluid. This can be done by leaving a catheter in the bladder and giving the patient three or four liters of distilled water to drink in the 24 hours. Salol, 1 grain three times a day, is useful. When the urine has become free from bacteria 20 c.c. of a 1 per cent. solution of nitrate of silver are injected into the bladder and the catheter is withdrawn. There is no object in washing out the renal pelvis through a ureteral catheter.

Indications for the Operative Treatment of Secondary Suppurative Labyrinthitis and Method of Treatment

Dr. E. Schmiegelow, Cophenhagen: The paper is based on the observed results of 42 cases of labyrinthitis following purulent conditions of the middle ear. In ten cases the labyrinthitis was either of the partial circumscribed or else of the serous type, and the patients all recovered after opening and emptying the cavity of the middle ear. The remaining 32 cases consisted of diffuse purulent conditions of the labyrinth with complete deafness. An operation on the labyrinth itself was not indicated in all the cases of secondary lesions of the labyrinth; the indications for this operation were not derived solely from the results of functional exploration, but also from the progress of the illness and the direct examination of the wall of the labyrinth after the radical operation. The treatment of secondary labyrinthitis consisted sometimes in efficient prophylaxis and sometimes on making an opening into the cavity of the labyrinth. The labyrinth may be opened in various ways. The method recommended by Jansen and Neumann ought not to be the principal one. This operation is deep and difficult, and is only justifiable when there is reason to suppose that in addition to the disease of the labyrinth there is suppuration in the posterior cranial fossa. The labyrinth may be opened with a drill (*fraise*), but the chisel and hammer are safer and enable the direction to be judged better. The method suggested by Uffenorde avoids accidental injuries to the facial nerve, which is exposed by carefully opening the aqueduct of Fallopius, and after this the semicircular canal, the vestibule, and the cochlea are opened. In this manner the facial nerve can be preserved during the complete removal of the labyrinth. At the end of the operation the nerve can be seen descending freely through the cavity which is left. In 22 of the 32 cases of purulent diffuse labyrinthitis the treatment consisted only in performing the radical operation on the middle ear. Of these 22 patients 2 died from complications existing previously to the operation. Of the remaining 20 patients 2 died, while 13 (i.e., 65 per cent.) recovered.

Infantile Types of the Temporal Bone and Their Surgical Importance

Mr. Arthur H. Cheatle, London, Eng.: By infantile type is meant the persistence in an exaggerated degree throughout life of the anatomic conditions of the outer wall of the antrum and mastoid mass as seen in infancy. In the adult the mastoid mass is generally diploetic but very rarely dense; the outer wall of the antrum is always dense and thick and lined internally by the cells which form before birth ("fetal cells"), and a layer of dense bone separates the cavity of the antrum from the mastoid mass. The types are found in about 20 per cent. of normal bones. The lateral sinus is usually forward. The density of the outer antral wall so frequently found in chronic suppuration in the antrum is a factor in producing chronic suppuration and is not an osteosclerosis.

Nasal Asthma

Dr. M. Grossmann, Vienna: Experimental researches undertaken in the hope of explaining the phenomena of nasal asthma have shown that electrical or mechanical irritation of the nasal mucous membrane leads to a notable disturbance of the cardiac function, followed by a considerable engorgement of blood in the pulmonary circulation and by an increase in the external dimensions of the lung. In curarized animals this increased volume of the lung causes a rise of pressure in the intrathoracic space and a depression of the diaphragm. This effect of nasal irritation is absent if either the second branch of the trigeminus nerve or the two vagus nerves are previously divided. There is, therefore, reflex action in a curved path the centripetal portion of which is formed by the vagus. This enlargement of the lung is not caused exclusively by the accumulation of blood, but also by the fact that the pulmonary capacity—i.e., the available pulmonary area—is increased in direct proportion to the engorgement with blood. The lung becomes larger not only as regards its external dimensions, but also as regards its intrapulmonary capacity. In accordance, herewith, the intrapulmonary pressure, unlike the pressure in the intrathoracic space, falls when the pulmonary circulation is engorged with blood. This enlargement of the lung is accompanied by rigidity which seriously interferes with respiration.

Treatment of Chronic Glaucoma

Dr. Felix Lagrange, Bordeaux, France, reviewed all the means, medical, surgical, and operative, which have been employed in the treatment of glaucoma, and laid particular stress on operations designed for lessening ocular tension. He dealt with iridectomy and sclerotomy as well as section of the sympathetic, and gave it as his opinion that all the intraocular operations only succeeded imperfectly in attaining the object of the perfect operation—namely, a fistulous or filtration cicatrix by which evacuation can be effected when the tension is too high. He described his operation for this end in precise terms. It consists essentially in a sclerectomy made at the level of the canal of Schlemm, and comprising all the thickness of the sclerotic. The incision should be made in such a way as to cut the insertion of the ciliary muscle, by which means the choroidal space will be brought into communication with the anterior chamber. The section of the sclerotic opens a free passage for the intraocular fluids, which can thus drain out under the conjunctiva. Dr. Lagrange added that in eyes with permanently increased tension sclerotomy should be followed by an iridectomy in order to avoid the inclusion of the iris. In cases of simple chronic glaucoma in which the increase in tension is intermittent or very slight, simple sclerotomy should suffice to produce an effective filtration cicatrix.

Postoperative Inflammations of the Eye Caused or Prompted by Autoinfection

Dr. Angelucci, Naples: It is an axiom of the present time that autointoxication and autoinfection are able to initiate inflammatory processes in the eye. Morbid conditions, often obscure and sometimes inappreciable to the patient, may cause postoperative inflammation in the eye. 1. Diseases of metabolism—(a) Albuminuria: Sclerosis of the renal vessels in old people and the arthritic kidney, accompanied by a slight excretion of albumin, have no deleterious effect on the postoperative course in cataract extraction. In Bright's disease iritis occurs almost always, sometimes after simple iridectomy, especially if the disease is advanced. (b) Diabetes: Cataract extraction may be free from inflammatory complications and consecutive hemorrhage in diabetics of good constitution. In the late dystrophic stages, usually associated with albuminuria, even if the sugar excreted in the urine shows diminution in quantity untoward results are to be anticipated. (c) Gout: This disease affords no contraindication to cataract extraction. Gouty attacks occurring during the period of convalescence do not appear to exercise any malign influence. When gout is accompanied by constipation or other disturbances of the intestinal tract there is not the same immunity from inflammation. 2. Diseases of the mouth.—In these cases iritis is common after extraction of cataract and may eventuate in suppuration. 3. Affections of the gastrointestinal tract.—Constipation and disorders of digestion are a potent cause of postoperative iritis. It occurs from the fourth to the eighth day and is ushered in by increased conjunctival secretion, often affecting both eyes. 4. Diseases of the bladder.—Two cases of iritis in iridectomy were associated with chronic vesical catarrh in spite of minute precautionary measures. Extraction of cataract has been followed by hyperemia of the iris although serotherapy was employed. 5. Influenza.—A case of cataract extraction during an attack of influenza resulted in the loss of eye from panophthalmitis. 6. Furunculosis and abscesses.—Hypopyon ulcer supervened on an iridectomy in a patient with boils, and the eye was lost from panophthalmitis in an old man who had an abscess and was operated on for cataract.

Prevention of Infection in Operations on the Eyeball

Dr. Elschnig, Prague, Bohemia: Investigations have led to the conclusion that in spite of careful antiseptic or aseptic precautions postoperative infection originates exclusively in the conjunctival sac, with the sole exception of rare endogenous infections. In all cases, therefore, in which the globe is to be opened the bacteria of the conjunctival sac should be examined and operation undertaken only if pathogenic organisms, especially streptococci and pneumococci, are absent. The most reliable methods are by culture experiments on both solid and fluid media, such as serum bouillon and serum agar plates. The use of pyocyanase and perhaps mercury oxycyanate is most to be recommended for the elimination of pathogenic organisms. Immunization procedures and even disinfection of the field of operation have little or no value, but general infection and disease of other organs must be treated. When infection of the conjunctival sac is suspected, the greatest care must be exercised as to the exact mode of operative procedure. All wounds should be situated in the conjunctival area, and wounds of the sclerotic with scissors—e.g., subconjunctival cataract extraction—should be avoided.

Eye Symptoms in Disease of the Pituitary Body and Acromegaly

Dr. W. Uhthoff, Breslau, Prussia: Cases of hypophyseal tumors with and without acromegaly were distinguished for purposes of differential diagnosis. The results given are founded on 328 necropsies. Temporal hemianopia is the most constant symptom; typical choked disc and slight papillitis each occurred in about 5 per cent. of the cases, simple atrophic pallor of the discs in 20 per cent. and central scotoma only in occasional cases. Paralysis of ocular muscles, generally affecting the oculomotor nerve, occurred in 10 per cent. of cases, and nystagmus in 6 per cent.

Sanitary and Hygienic Organization of Armies, with Especial Relation to the Spanish Army

Dr. Larra y Cerezo, Madrid, Spain: Each division of the Spanish army will take into the field a complete hospital with every necessary appliance for 200 beds, distributed among 16 tented-wagons. As a complement to this hospital installation the division is further equipped with 4 wagons, each containing surgical and medical appliances, each with 300 dressings, and the pharmaceutical necessities and material for clinical investigation in the hospital; 4 wagons of appliances, a food-supply wagon, which provides food for the hospital of 200 cases for six days; and 24 ambulance wagons. These units correspond to the divisional field ambulance and the divisional hospital. The latter has also at its disposal a disinfecting stove, bath, apparatus for sterilization by heat and by ozone, a reservoir wagon of water with a filter, and another for chemical and bacteriologic analysis and for radiographic investigation. In the regiments the material for sanitary service include the following sealed patterns: (1) A first field dressing for each man; (2) an emergency knapsack for each company; (3) a medical saddle-bag or wallet, for each squadron or battery; (4) a medical haversack; (5) a medical chest per battalion; (6) a reserve chest for each battalion; (7) a medical vehicle for each battalion; (8) a case of surgical instruments (9) a case of amputation instruments for mounted corps; (10) a service stretcher; (11) a Swedish chair; (12) an ordinary litter. Each army corps has a hospital train. Spain has three large establishments to provide the raw material, and sealed patterns of material, including vaccines, prophylactic and therapeutic serums, drugs, etc. These establishments are: The *Military Health Park*, the Central Medical Laboratory, and the Institute of Military Hygiene. All the sanitary units assigned to each division in time of war are calculated to provide the division with about 46,000 to 49,000 dressings—that is, 3 per head, 1 first field dressing, and 2 for secondary treatment.

Intestinal Parasites in the Tropics

DR. DEBAYLE, Nicaragua, dwelt on the extreme frequency of diseases due to such parasites in tropical countries, particularly the ankylostoma, the *Ascaris lumbricoides*, the *Trichocephalus dispar* (the serious effects of which are often not sufficiently recognized), and the various forms of tenia. The symptoms are protean in their character, they result from a severe toxemia; the hemolytic effect of the toxins was specially dwelt on. There is the real need for energetic measures in destroying these parasites; the people must be educated, an active propaganda is essential.

Epidemics of Dysentery in the Mussulman Pilgrimage

DR. ARMAUD RUFFER, president of the Maritime, Sanitary, and Quarantine Board of Alexandria: At the Egyptian lazaret of El Tor from 400 to 600 individuals with dysentery are treated each year among the returning pilgrims, and of these some 150 die. As the pilgrims at El Tor represent only a portion of the whole number, it is evident that the deaths from dysentery during these pilgrimages must be enormous—perhaps from 3,000 to 15,000 per annum. It is unfortunate that the same attention has not been paid to this disease by the European powers as to plague, or cholera, or yellow fever; the international sanitary conventions deal only with the latter diseases. There are two main forms of dysentery, the amebic and the bacillary, and not infrequently a mixed infection is encountered. From observations made at El Tor conjointly with Dr. Zirolia, it was found that the majority of the patients gave no serum reaction with the Shiga-Kruse bacillus; in fact, only 2 per cent. of the whole gave such reaction. In some of the cases the Flexner organism was present, in others the pseudodysenteric bacilli, A and D, of Kruse, were found. Each of these organisms was absolutely distinct, and gave reaction specific to itself but not to the others. In a number of patients another bacillus was found, to which the name of the Tor bacillus, No. 1, has been provisionally given. All these organisms presented the general characteristics of the pseudodysenteric bacillus D of Kruse, but their serum reaction was entirely different; they agglutinated neither that nor any other of the above-named bacilli. Briefly, the forms of dysentery encountered in the pilgrims are due to at least nine different micro-organisms, and at least six bacilli are more or less clearly and distinctly differentiated. In cases due to the Shiga-Kruse bacillus most excellent results have been obtained by serotherapy; indeed, in few other diseases are the results of serotherapy so brilliant. In the Tor cases there was practically no effect, which is further evidence that they are due to some other micro-organism.

Yellow Fever Prophylaxis in Cuba

PROFESSOR AGRAMONTE, Havana: The topography and geographical position of Cuba and its large, non-immune population render it, if not less liable to invasion by the disease, at least more favorable to its extinction than some other regions. In 1901 the infection completely disappeared, as the result of a campaign based on the doctrine of mosquito transmission, and carried out by Colonel Gorgas. Between February, 1901, and October, 1905, only a few cases of the disease, imported from Mexico or South America, occurred and none of these gave rise to secondary cases. In May, 1902, the republic was inaugurated; the flow of immigration, especially from Spain, increased twofold, and the new railroad brought one end of the island into rapid communication with the other. New towns were established and trade and industrial enterprise increased proportionally. Three unfavorable results followed: An unwarranted sense of security was brought about, the non-immune population was increased, and the *stegomyia* mosquito was spread from the coast to the interior, where it did not exist before. Consequently, the yellow fever epidemic of New Orleans in 1905 crept into Cuba in October of that year, and from that time till Dec. 24, 1908, 405 cases of the disease developed in the island. None has occurred since. The measures employed to deal with this outbreak were indirect and direct. Quarantine appears to be of small value in the prevention of yellow fever, if the certificates of immunity presented by passengers be relied on. In 1905 close quarantine was in force against the southern states of America, and yet the infection, which was waning in New Orleans, entered the island. An absolutely closed quarantine might be effective, but it would cause great inconvenience to commerce and to travelers. The isolated and complete defense against mosquitoes of all imported cases, on the other hand, are effective, as shown by the occurrence of more than 30 imported cases from Mexico and the United States, without any secondary cases developing. The patients were all isolated in the Las Animas Hospital, where the most minute precautions are taken to prevent the spread of infection by mosquitoes. Every hospital in the island is provided with yellow fever wards. A system of registration of non-immunes has also been most useful. Some 60,000 men are registered as members of various five specially equipped hospitals. These 60,000 men are under Spanish clubs or societies in Havana; and for these there are special sanitary control, and any suspicious illness among them is at once dealt with. As the total number of white foreigners in Havana is 74,000, it will be seen how valuable a measure this is. Similar societies exist in other towns. Spanish immigrants rarely fail to inscribe their names with one or other society. A large staff of sanitary commissioners has been formed, and these investigate any suspicious case in any part of the island. Among the direct measures in the control of yellow fever one of the most important has been a house-to-house inspection carried out by trained men every ten days. The removal of breeding-places for mosquitoes, the oiling of pools and other collections of water and the provision of metallic gauze coverings to water-tanks and barrels, have been extensively carried out. Another useful measure has been the free distribution of fish to be put into such barrels and tanks in order to destroy the larvæ. Fresh supplies of fish are furnished as required. The destruction of mosquitoes by fumigation or other means is also extensively applied.

Etiology and Prophylaxis of Bacterial Dysentery

DR. GALLI-VALERIO, Lausanne, Switzerland: The disease is caused not by one bacillus but by many bacilli belonging to the Shiga group of such organisms. The terms paradysentery and pseudodysentery should not be used, as they tend to cause neglect of measures of prophylaxis. The disease is spread mainly: (1) by personal contagion either from sick persons or from healthy "carriers" of the bacilli, and either directly or through fomites; (2) by water, which plays a most important rôle in the spread of the disease; (3) by means of flies, as proved by experiments; (4) by milk, which may be infected by flies or by the addition of infected water, or the washing of vessels with such water; (5) by vegetables, for similar reasons; (6) by the soil and dust. The main prophylactic measures recommended are grouped under the following headings: (1) as rapid as possible a diagnosis of the first cases; (2) compulsory notification of all cases; (3) strict isolation of the sick; (4) disinfection of the excreta, of linen and other fomites, and of the room occupied by the sick. Immediate and compulsory notification, at present in force in few countries, is an absolute necessity. Thorough sanitation is also, of course, of prime necessity; and finally, the public must be actively educated in the need of strict measures. Vaccination has hitherto given uncertain results.

Pathology of Secretion and Motility of the Intestinal Canal

DR. A. BICKEL, Berlin: Disturbances of the glandular activity in the intestine can be either quantitative or qualitative in their effects, the former depending on alterations in the production of the secretions, and the latter on their composition. The disturbances may therefore be distinguished respectively as parenchymatous or neurogenous. In the first named the morbid process affects the gland cells or the surrounding tissues; in the second form the nervous mechanism of the gastro-intestinal tract is the seat of the disturbance. Further, the alterations in the secretion of mucous must be distinguished from that of the secretion of the digestive juices. With regard to the former an excessive secretion only is of importance; this is due to some fault in the parenchyma; the nervous supply may also have an influence through a less powerful one.

Medicolegal

Power of School Boards to Enact and Enforce Rules to Prevent Appearance of Smallpox in Schools and Especially Requiring External Vaccination

The Supreme Court of Missouri says, in the case of State, on the relation of O'Bannon vs. Cole and others constituting the School Board of Sedalia (119 S. W. R. 424) that the board, on Dec. 4, 1908, made an order that it had come to the knowledge of the board that smallpox existed within the school district, the board deemed it necessary that all children attending school, who had not been vaccinated, must be vaccinated within 30 days. On Jan. 8, 1909, the board adopted the following additional resolution: The board will not accept a certificate of vaccination unless the physician does state that the child has been vaccinated with vaccine virus, and all children who have had smallpox must bring a certificate from the physician in attendance to that effect; and, where such certificate can not be procured, then the parent or guardian must make affidavit that such child has had the smallpox, etc. The records of the board showed a called meeting held on January 12 for the purpose of taking further action on the question of vaccination, the president stating that he had been informed that certain physicians had been vaccinating school children by giving powders internally and giving them certificates that they had been vaccinated internally with vaccine virus. A physician present asked to be heard on the subject and stated that such treatment would render the patient immune from smallpox. A resolution was then passed: That no certificate of vaccination shall be received unless the same states that the person was vaccinated externally with vaccine virus.

O'Bannon's two children were excluded from the schools of the district in January, 1909, under the above rules, and because they had not been vaccinated as required by the rules. Then this suit was brought. The trial court granted the writ desired, and declared said rules void. The Supreme Court holds that such judgment was erroneous, and reverses it.

The Supreme Court agrees with the board of directors that under the general statutory provisions they had the inherent right to promulgate and enforce the orders and rules in question. The precise question, the court says, has never before been before it, but has been before the St. Louis Court of Appeals in the case of the matter of the application of Rebenack for a writ of mandamus against the board of education of the city of St. Louis, 62 Mo. App. 8, which has been cited with approval in Indiana, Massachusetts, Minnesota, North Carolina and Utah cases.

The Supreme Court has no doubt that, in the event of a threatened epidemic of smallpox, boards of school directors can pass a rule excluding all pupils who have not been vaccinated. That a person who has never been vaccinated is subject to the contagion of smallpox is general knowledge. That vaccination has reduced the ravages of this disease is also general knowledge. That the appearance of unvaccinated pupils in a public school at a time of a smallpox epidemic would tend to break up and disorganize a public school is unquestioned. That the school board has the power to absolutely suspend the school during epidemics of contagious or infectious diseases, the court thinks can hardly be questioned. No court would compel the opening of a school under such circumstances. The power here exercised was a very similar power, and, if these rules were reasonable, this court sees no reason why their enforcement should be prohibited.

The Illinois rule does not go to the extent of holding that a board of education, in case of a threatened smallpox epidemic, could not exclude pupils who had not been vaccinated.

The courts may be somewhat divided on the question as to whether or not vaccination, under all conditions and at all times, may be made a condition precedent to a child attending a public school; but the courts are practically a unit in holding that in the event of a present or threatened epidemic, such rules are reasonable and should be upheld by the courts. And such has been the rule in states where there is no express authority requiring vaccination. Many states have passed laws requiring vaccination of pupils before entering schools, and these have been generally upheld, and that, too, in the face of statutory and constitutional provisions making such schools open to all pupils within the required ages.

This court will not go further on this branch of the case. Nor will it go beyond the case in question. For years there had been smallpox in Sedalia. Within two weeks of the trial in the lower court there were yet cases there. At the promulgation of the rules in question, there were a number of cases, so there was not only a threatened epidemic of the disease, but an epidemic itself. This court is of opinion that school boards in Missouri, in the event of a smallpox epidemic, or a threatened smallpox epidemic, have the right to enforce such rules as were enforced in this case, unless they are precluded therefrom by other statutes now to be considered.

It was contended that, by reason of the compulsory school act, the rules in question would enforce this parent to violate that law, and that under that law the rules enforced by the school board were void. That act, however, in no way affects these rules. In the first place, there can be no prosecution of a parent for failing to send his child to school under that act until after an officer of the school district has notified him to send such child, and then, if he fails, a prosecution can be had. This parent was in no danger of violating that law. The act makes it a misdemeanor to violate its provisions, and this court has yet to hear of a criminal case wherein a defendant was convicted of willfully violating a law, when in fact he has manifested the disposition that this parent had to comply with the strict letter of the law; but, laying aside all levity, the act of the school board, whose officer must initiate the prosecution by giving notice, would be an absolute defense. Beyond all this, the compulsory school act must be construed with the whole body of the school law, and when so construed, it can be made to harmonize therewith to the end that there would be no violation of the law. The court is of the opinion that there is no real conflict between rules of the character involved in this case and the compulsory school act.

But Section 9765 of the Revised Statutes of Missouri of 1899 was chiefly relied on as the battering ram by which these rules of the school board were to be demolished. An analysis of that section shows: (1) It prohibits a child afflicted with a contagious or infectious disease, or one exposed to such a disease and liable to transmit the same, from attending a public school; (2) for determining either its diseased or exposed condition, either the teacher or school board may require the child to be examined by a physician; (3) such child may be excluded so long as there is danger of transmitting such disease; (4) a refusal on the part of the parent or guardian to permit such child to be examined authorizes the exclusion of such child from the school; and (5) if the parent or guardian shall persist in sending such child to the school, such act is made a misdemeanor and a punishment is affixed. This analysis of the section shows that it is dealing wholly with a case where a child is actually diseased, or has been exposed to a disease of the character named. The statute does not undertake to abrogate the general power to control the school given to the board of directors, nor does it undertake to deal with the subject of needful rules. One main purpose of this Section 9765 is to provide a punishment for that class of either careless or persistent parents who are willing to inflict on others the diseases and troubles of their own children. The first part of the statute, as said, deals with a concrete case of a diseased or exposed child; but by no maxim, or other rule of construction, can this court see how it can be said that in the enactment of that statute there was a legislative intent to preclude a school board from enacting reasonable rules to prevent the appearance of contagious or infectious diseases in the schoolroom. The rules in question in this case were enacted to prevent the appearance of disease in the school. This the school board can do, so long as its rules are reasonable, under the general power.

This court is, therefore of the opinion that the school boards of Missouri have the right to enact and enforce rules of the character here in question at all times whenever there is either a smallpox epidemic in the district or whenever there is a threatened smallpox epidemic. The very purpose of such regulations might be thwarted were the epidemic itself to be actually awaited.

1. **Practical Diet Charts.**—In the preparation of these charts Arnold has aimed to give on one sheet of paper all the data necessary for arranging and calculating the nutritive value of a diet, and to furnish a convenient means of recording the results. The feature which makes these charts practical for use is the information given as to the nutritive value of food in measures such as are used in everyday life. A fairly accurate record may thus be obtained with very little inconvenience to the patient. The tables give the composition of ordinary articles of food. The values are approximate only, but are sufficiently accurate for practical use. The tables are based chiefly on Atwater and Bryant's statistics. Arnold shows that scientific work in connection with the diet must be based on the caloric value of foods, and the amount of each of the three ingredients (protein, fats and carbohydrates) contained in the food. The quantitative regulation of food is as important as its qualitative regulation. These charts give all the data needed in the practical regulation of the diet in such a form that calculations can readily be made and the results can be conveniently recorded.

4. Abstracted in The Journal, July 24, 1909, p. 317.

5. **Ocular Tuberculin Reaction.**—In a series of cases at the Colon Hospital in which the ocular reaction was tried by McCarthy, the test was applied to various diseases besides tuberculosis. Two hundred and sixty-three cases were tested, and the results have been satisfactory as compared with the reports of other observers. Sixty-four cases of pulmonary tuberculosis were tested, with 54 positive reactions and 10 negative. In the first stage of the disease 22 cases were tested and all were positive, 100 per cent. In the second stage, 12 were tested, with 11 positive and 1 negative reaction. In the third stage, 30 were tested, with 21 positive and 9 negative reactions. Forty-five patients had positive sputa. Fifteen patients had negative sputa, and 4 raised no sputum. Of 3 cases of miliary tuberculosis tested, 2 gave positive reactions and 1 negative. Of 20 cases of clinically suspicious tuberculosis, 12 gave positive reactions, with 8 negative ones. Most of these patients had suspicious physical signs in the chest, some had slight rise of temperature, emaciation, night-sweats and cough. In 25 patients not considered tuberculous, but with obscure temperatures and no signs of tuberculosis clinically present, 21 were negative and 4 positive to the test. Of 8 cases of acute bronchitis and 6 of chronic bronchitis, no positive reactions occurred. Of 9 patients with pleurisy with effusion and 7 with pleuritis sicca, 1 of each failed to react, showing 14 positive reactions out of 16 cases. There was 1 positive reaction in 3 cases of bronchial asthma tested; 2 cases of pneumothorax reacted positively. Fourteen cases of lobar pneumonia were tested, 4 of which were unresolved; negative results were obtained in every case. One case of bronchopneumonia in an old man gave a positive reaction, although the sputum was negative. In 16 cases of malarial fever, all complicated with bronchitis, amebiasis, uncinariasis and other conditions, 14 patients failed to react, with 1 positive result. Of 19 cases of typhoid fever, 8 gave positive reactions and 11 negative. Of the 8 positive cases there were 3 blood cultures taken, all showing the *Bacillus typhosus;* in the other 5 no blood cultures were taken. In the 11 negative cases of typhoid, all had blood cultures, 3 showing the paratyphoid bacillus, 3 the para-colon bacillus, 1 the *Bacillus typhosus* and 3 bacilli in the typhoid group. In 4 cases of tuberculous bone disease, 2 of Pott's disease, 1 each of tuberculous knee and tuberculous elbow, there were four positive reactions. Of 3 cases diagnosed as tuberculous adenitis, 2 cervical and 1 inguinal, all gave positive reactions.

In a group of miscellaneous diseases the following were negative: 1 tabes dorsalis, 1 syphilitic periostitis, 2 chronic nephritis, 1 cirrhosis of liver (with chronic diarrhea), 2 gonorrheal arthritis, 1 filariasis with chronic nephritis, 1 hemoglobinuric fever, 1 empyema, 1 chronic heart, 1 traumatic rupture of lung with hemorrhage, 3 epidemic cerebrospinal meningitis, 1 leprosy, 1 syphilis (secondary), 3 acute nephritis, 3 amebic dysentery, 1 relapsing fever, 1 cystic kidneys, 2 chronic diarrhea, 4 uncinariasis, 4 liver abscess, 1 ulcer of foot, 2 arthritis (obscure), 1 each of alcoholic neuritis with rise of temperature, T. B. kidney, chronic nephritis, pericarditis and perinephritic abscess—42 cases in all.

Five miscellaneous cases gave positive reactions: amebic dysentery with temperature, posttyphoid arthritis, blastomycosis dermatitis, hematuria, aortic aneurism with bronchiectasis. Nine normal individuals gave negative reactions.

6. **Modification of the Thomas Wrench.**—For cases which do not yield to either manual force or the ordinary wrench, Meisenbach has devised a modification of the Thomas wrench whereby the os calcis, as well as the tarsal bones, are under the control of the operator and by means of which force can be exerted with as great accuracy and precision as is desired. The wrench is applied in a similar way to the Thomas instrument, but, before the force is exerted, the strap is wound around the external aspect of the os calcis and tensely adjusted to the hook on the opposite arm of the wrench. The wrench is applied from the external aspect of the foot, when external force is desired, and vice versa when internal force is the object. In applying the wrench, it should be approximated firmly to the foot, and care should be taken to fasten the strap firmly before any force is applied. The wrench itself is made similar to the Thomas wrench, to the lower arm of which is attached a strap about 60 cm. long with holes. On the corresponding arm there is a hook whereby the strap may be attached at any length desired. The author has used this wrench with great success in obstinate cases that have not yielded to other methods.

11, **Uncontrollable Uterine Hemorrhage.**—Samuels reports two cases of uncontrollable uterine hemorrhage in which hysterectomy was performed.

15. **Gonococcus in Prostate.**—Of 150 cases of chronic gonorrheal infection of from 6 months to 18 years' duration, 6 per cent. showed prostatitis. The older the infection, the more frequent was the prostatitis. Of the 108 cases of prostatitis studied by Saxe, 31, or 28.7 per cent. showed gonococci in the prostatitis secretion. The older the infection the less probable was the finding of gonococci in the prostate. After three

years, gonococci were found rarely, even after most persistent efforts. Many and thorough examinations are needed before it is at all certain that the gonococcus is absent from the prostate. Mixed infection occurred in 86 per cent. of the cases studied. The gonococcus alone occurred in only 5 cases of 108, and all 5 were cases of less than one year's duration. The older the case the more prevalent was the mixed infection. Staphylococci occurred in 74 per cent., bacilli in 28 per cent., Gram positive diplococci in 10 per cent., and streptococci in 7.6 per cent. of cases with mixed infection. The absolute need of microscopic examinations of prostatic secretion was shown by the fact that palpatory signs were absent in 38 cases (35 per cent.), while 13 cases (12 per cent.) showed absolutely clear urine, although the smears showed prostatic infection. Saxe claims that gonorrheal prostatitis is curable by proper treatment in the great majority of cases.

16. **Treatment of Locomotor Ataxia.**—Fruchthandler describes fully a method of treatment based on the Frenkel method, but without the use of complicated devices. His results have been gratifying to him. For details the reader is referred to the original article.

20. **Round Ulcer of Stomach.**—Work claims that in the causation of the typical round ulcer of the stomach there is: (1) A neutralization of the natural protective bodies current in the blood stream and tissues; (2) the elaboration of either an endogenous or exogenous cytolytic poison which is specifically toxic for gastric mucous membrane; and (3), as a result of these factors, a neurosis and desquamation of actual glandular tissue of the stomach takes place which is accompanied by a lack of gastric mucus and a large increase in the hydrochloric acid.

26. **Simpson and Chloroform.**—Robinson gives a graphic account of the surroundings and birthplace of James Simpson, who first made use of chloroform in labor.

28. **Removal of Tonsil.**—Sheedy says that tonsils in the young serve an important purpose and should not be removed unless they are so far diseased that their normal function is interfered with. In such cases they no longer act as a fortification and protection against bacteria, but may become the means of entry of these enemies to health. Immunity is produced by the tonsils; natural immunity is caused by inflammations, and artificially acquired immunity is produced in the tonsillar crypts by agglutination and the development of opsonic power.

29. **Influence of Diabetes in Operations on Eye.**—Of 115 operations, 62 were cataract extractions, 40 were preliminary iridectomies, 9 were iridectomies for optical purposes, owing to the presence of central corneal opacities, and 4 were iridectomies for chronic glaucoma. Of the 62 cataract extractions, 40 were senile cataracts in diabetic patients, and all the patients were 65 years of age or over. These were all extractions with iridectomy, and all the patients recovered without any serious complications, though the wound healed slowly in 11 cases. There were no hemorrhages and no sign of infection in any of the cases. Ten cases showed slow healing of the wound, and all gave evidence of arterial degeneration and a high intravascular tension. The remaining 22 cases were all pure diabetic cataracts; that is, they were cortical cataracts, bluish-white in color, and somewhat swollen. The patients' ages varied from 36 to 40 years. In each case, before operation, care was taken to reduce the percentage of sugar to a minimum and, so far as possible, to eliminate the abnormal products, acetone, diacetic acid and oxybutyric acid. In 6 of the 22 there was a somewhat profuse hemorrhage into the anterior chamber, which recurred several times. In 2 cases there were retinal hemorrhages, which did not recur and were slowly absorbed. In 6 cases the operation was followed by iritis, without much exudation, which was obstinate in resisting treatment, and a discission of the opaque capsule was necessitated in 2 cases. In the remaining 8 cases there were no complications, either at the time of the operation or following it, and the wounds healed promptly with excellent results as to vision. In 14 of the 22 cases there were signs of arteriosclerosis in the conjunctival vessels, and after the extraction of the cataracts the same condition was found in the retinal arteries. In the remaining 8 cases arterial degeneration was demonstrable. In the second list of operations 40 cases of preliminary iridectomy in cataract patients, 22 were senile cataracts in diabetic patients, whose ages varied between 60 and 68, and 18 were true diabetic cataracts in patients under 40 years. In the 22 cases of senile cataracts no case of iritis occurred after the iridectomy, but in 3 cases there was an annoying hemorrhage into the anterior chamber and the external wound healed very slowly, and in these 3 the signs of arteriosclerosis were present. In the 18 cases of true diabetic cataracts iritis occurred in 4 cases, but owing to prompt treatment no permanent synechiæ were formed. In the third list of operations there were 9 iridectomies for optical purposes, owing to central corneal opacities. There were no anterior or posterior synechiæ and no signs of intraocular irritation. They were all young diabetics, under 40, and with one exception, all did well, the wounds healing promptly. In all 9 patients the fellow eye was normal. In the fourth and last class of operations there were 4 iridectomies for chronic glaucoma performed before the field of vision was much contracted. All 4 patients did badly, and 1 patient fell into collapse and nearly died. Three were men and 1 was a woman. Profuse hemorrhage into the antĕrior chamber occurred in all 4 cases, and recurred several times, but there were no retinal hemorrhages. In the fourth case, a woman aged 59, there was a profuse hemorrhage into the anterior chamber. Eight months later the patient succumbed to an attack of diabetic coma.

31. **Tuberculin in Renal Tuberculosis.**—Karo says that tuberculin is of great value in the treatment of renal tuberculosis, and that no such patient should be operated on until this treatment has proved a failure. Even after the operation the tuberculin treatment is of utmost importance.

34. **Staining of Blood Films.**—The most uniform results have been obtained by Fisher from a slight modification of Jenner's stain, which requires the use of no other apparatus than the staining solution and slide, and is prepared after the following formula: Take 200 c.c. of a 1.25 per cent. solution of yellow aqueous eosin in distilled water and mix with 200 c.c. of a 1 per cent. solution of methylene blue, medicinally pure, Grübler, in distilled water. Allow this mixture to stand in an uncovered shallow porcelain evaporating dish for from 24 to 36 hours, protected from dust, then filter through a fine-grained filter paper; dry the residue in the incubator or oven at from 55 to 60 C. This powder is shaken up with cold distilled water, filtered through fine paper, and washed with distilled water until the washings are a thin, dirty, purplish color. Dry the precipitate on the paper, either in the air or in the oven, not above 60 C., then scrape off the powder and store in a bottle. This gives enough powder for from 300 to 400 c.c. of stain. Take the above powder, 0.2 gram, and of methyl alcohol (acetone free), 100 c.c. Rub up in a mortar, adding the alcohol to the powder, a drop at a time, allow to stand for 3 or 4 days in a bottle, then filter and add 25 c.c. of methyl alcohol. The bottle should be corked tightly to avoid evaporation and consequent concentration of the stain, but the solution may be diluted later with another 25 c.c. of methyl alcohol if necessary. Make blood films on slides, dry quickly in the air, and cover with a thin layer of the staining solution without previous fixation. Stain

the slide for from one to three minutes, then wash with some of the original solution, removing any possible precipitation and intensifying the stain. Next wash in running water until film is a mahogany color. Dry with filter paper. It is impossible to overstain. The red cells are stained a terra cotta; stippled cells are easily detected by the minute bluish markings; nuclei are blue and sharply defined; blood platelet in clumps are a paler blue, but quite distinct; granules of the polymorphonuclears are a dull mahogany; granules of eosinophiles, a brighter mahogany; basophilic granules are bluish violet; malarial parasites are stained a greenish blue; the pigment of the pigmented forms is unaltered, and the ordinary bacteria are stained blue. This method of staining is used in counting bacteria for vaccines and the opsonic index.

48 Postoperative Insanity. I. Abell, Louisville.

46. **Infantile Paralysis.**—About the middle of July, 1909, Frazier saw a young girl, 14 years old, who, about five or six days before, had suffered from a mild digestive disturbance. She had a temperature of 99 F. and it ranged from that up to 101; no diarrhea and no vomiting. Five or six days later she had become paralyzed. The history was that during the night this girl had awakened her mother and asked the latter to take her hand out from under her, as she had lost the power to do so. In the morning it had extended to the left leg and foot, and a few hours later she could not move the right hand or foot. One unusual feature of the case was in connection with the family history. The mother was 49 years of age when the child was born and the father was about 58 or 60. This was the first and only child. The child had been healthy, had grown rapidly, and had gotten along well at school; had none of the usual diseases of childhood. When this attack begun it was thought to be a spell of indigestion. The girl was menstruating at the time, this being her third period, the interval between periods being several months. A diagnosis of anterior poliomyelitis was made.

Another point of more than ordinary interest was the fact that the patient was exceedingly sore and complained on being moved or handled. She had an unusual degree of insomnia. She slept scarcely at all during the first two weeks, and when moved would ask to be moved back again in ten or fifteen minutes. After the first few days she could draw her right hand up and take hold of an object, or when her foot was drawn up she could push it down, but it was weeks before she could sit alone. She is now able to sit up in a chair and can even hold a book in either or both hands. She can get her hand up to her head by putting it up backward, and can even stand alone when her father stoops down and places her knees together, but she cannot take a step with either foot yet. She can work her left foot along a little, and can raise one of her legs up straight; she can just bend her thigh, not the hip. She cannot turn over in bed unassisted. Occasionally she asks to have her legs crossed, and when she desires to have them uncrossed some one has to do it for her. She is well nourished and has a good appetite, and the condition of the bowels and kidneys is all right.

62. **A Year's Experience with Rubber Gloves.**—As the result of his experience, Fowler claims that gloves do not reduce the number of postoperative infections; the wound must be somewhat larger to allow of at least occasional visual direction; the tactile sense is decidedly interfered with, nor does the continued use of gloves educate the tactile sense anywhere near that of the bare hand. In his own case there was no difference as regards the condition of the skin of the hands. Manipulations are rendered slower and in some cases decidedly dangerous. The length of time of operation is decidedly increased, and, hence, there is added danger and shock to the patient. Assistants and nurses should wear gloves, as they are not so accustomed to preparation of the hands.

70. **Influence of Concentration.**—Anderson shows that concentration of antidiphtheritic serum by precipitation with ammonium sulphate and acetic acid, followed by dialysis, does not remove all the toxic impurities that may be in such serum, and that the foreign toxin is probably carried with the antitoxin in the globulin fraction.

71. **Relation of Thyroid Glands to Glycosuria.**—After thyroidectomy, the glycosuria produced by ether or adrenalin in the normal animal is greatly reduced. Thyroidless dogs fed with powdered thyroid gland show a return of the glycosuria

more or less proportional to the amount ingested when treated with ether or adrenalin. As the thyroids regenerate the ether or adrenalin glycosuria increases similarly. The experiments indicate that the secretion of the thyroid is connected directly or indirectly with the metabolism of the sugar in the body.

72. **Carbohydrate Metabolism.**—King finds that the thyroid retards the destruction of carbohydrates in the body and that iodothyrin, the active principle of the gland, exerts this influence even more strongly than the whole gland.

73. **Effect of Injection of Bile on Circulation.**—In experimental jaundice there is an increase of calcium in the blood: and the authors, finding that bile pigment in combination with calcium and sodium, is less toxic than uncombined pigment, are of the view that increase in calcium is a protective mechanism against the bile pigments of obstructive jaundice.

74. **Enzymes of Tuberculous Exudates.**—The observations here recorded show, as previously indicated, that the mononuclear epithelioid cells of tuberculous tissue contain an enzyme which digests protein actively in an acid and slightly less actively in neutral medium, being wholly inactive in the presence of alkali. Unlike the enzyme of the polynuclear leucocytes, this enzyme is not inhibited by the serum of tuberculous exudate obtained by injecting tubercle bacilli into the pleural cavity of a dog, although it is inhibited by the blood serum. The serum of such an exudate, unlike the serum of the blood, is capable of digesting denaturalized protein. The power of digesting protein has not been demonstrated in the serum of human tuberculous exudates.

76. **Proteolytic Enzymes and Antienzymes.**—The spinal fluid was found to contain normally neither proteolytic enzyme nor antienzyme. In pathologic conditions, however, enzyme and antienzyme may make their appearance in the spinal fluid. In inflammations of other serous cavities the antienzymes of the exudated serum as a rule is sufficient to restrain the activity of the proteolytic enzyme freed from the leucocytes, but in infections of the meninges with pneumococcus and *Streptococcus mucosus* free proteolytic enzyme was found in four of five cases. Free proteolytic enzyme has not been found in the spinal fluid in epidemic meningitis; antienzyme was found to have a tendency to disappear more rapidly than in other inflammatory exudates. In subdural non-inflammatory transudates the inhibitory element of the blood serum accumulates, suggesting an interference with the elimination of the antibody from the spinal fluid. In tuberculous meningitis the spinal fluid showed various degrees of antienzymotic action.

77. **Pneumococcus Infections.**—Strouse finds that phagocytosis of pneumococci *in vitro* runs parallel with phagocytosis *in vivo* and that the virulence of pneumococci depends not only on the results of phagocytosis but also on the ability to grow in the body of the animal. The immunity of the pigeon to pneumococcal infection is ascribed to its high normal temperature.

78. **Treatment of Sepsis.**—The 97 cases which form the substance of this report have been infections, mostly acute, with various bacteria, the ordinary pyogenic organisms. They form a miscellaneous collection which can best be described under the general term of "surgical sepsis," and include such diverse cases as septic fingers and hands, septic laparotomy wounds, and septicemia. In every case, the pathogenic organism was determined by culture, and in the majority an "autogenous" vaccine was used. In some cases two different vaccines were employed when it seemed probable that there was more than one offending bacterium. The vaccines were made up according to the method devised by Sir A. E. Wright, somewhat modified according to Mallory and Wright.

The amount of inoculation varied with the micro-organism and with the nature of the infection. The initial dose was from 5 to 25 millions, and this amount was gradually increased at each successive inoculation, as it is assumed that an increasing tolerance was attained. The maximum amount given was usually 100 million, although this was sometimes exceeded. In all cases, except the general infections, an arbitrary interval of three days was made between each two inoculations, that is, they were given every fourth day. Other spacing may be more effective, but this was followed in the boils and carbuncles, and seemed to afford the most satisfactory results. Eighteen patients with puerperal infections recovered. In some of the cases of puerperal infection the effect of vaccine on the temperature and general condition was less striking than in others. These were cases in which an abscess had formed, probably in the tubes, and they did not clear up until the pus was discharged by vagina.

Besides these puerperal patients, 9 general infections were treated; 4 were *Staphylococcus aureus* and 5 were streptococcus; 4 of these 9 progressed to a fatal termination. In the patients who recovered, the authors do not think the vaccine can lay claim to any further share in the successful outcome than the complete surgical treatment which was followed.

The second group, septic laparotomy wounds, comprise 22 cases. Nine of these were clean cases, which were infected secondarily; the remainder were septic and were drained from the beginning. *Bacillus coli* and *Staphylococcus aureus* were the organisms most frequently found, streptococcus came next, while one showed the pneumococcus. When the *Staphylococcus aureus* was found, a "stock" vaccine was used, with the others an "autogenous" vaccine. In some of these cases, when the wounds had remained stationary for some time, improvement seemed to follow immediately after vaccination. Not one patient of this group was dangerously ill, and they were all discharged from the hospital in good condition. In the third group there were 41 cases, largely septic fingers and hands, with some of the lower extremities, including the groin, and a few of the head and neck. These cases represent a class of varying degrees of sepsis. The patients all recovered, some after extensive incisions and some after mutilating operations.

The authors conclude therefore: 1. That bacterial vaccines should be further employed in puerperal infections which do not immediately respond to routine treatment. 2. That bacterial vaccines are of much value in that type of sepsis which has remained stationary for some time. 3. That in the remainder of the cases of this series they were not able to see that the vaccines were of any apparent help.

80. **Double Fracture of Patellæ.**—Morison emphasizes the desirability of using absorbable material in these cases rather than wire or other non-absorbable material. He says that with the patella sutured with catgut it would not be safe to allow movement of the knee in less than from four to six weeks. Morison has never seen permanent stiffness of the joint after this operation in any of his cases, though some of the patients were over 60 years old.

81. **Direct Blood Transfusion.**—The object of this communication is to record the results of some experiments undertaken with a view to finding some simple method of direct blood transfusion. A set of glass tubes were made, some of which were straight, with a uniform caliber, others bayonet-shaped, and still others somewhat tapering in shape and caliber, to be

used when transfusion was attempted from a large adult artery to the small vein of a child. Each extremity of the tube is notched to allow of a ligature being applied after the tube is introduced into the lumen of the vessel. These tubes should be sterilized in a steam autoclave or by boiling, and afterward dropped into boiling paraffin, and the excess of melted paraffin removed by shaking the tube in the air. This also results in rapid drying of the paraffin leaving a thin film on both the inner and outer surfaces of the tube. The paraffin adherent to the outer surface of the tube then is removed to allow more ease in handling.

Of 31 experiments only 3 animals died, each from a too-rapid transfusion of the blood, causing distention of the right heart. This accident occurred when the largest tubes were used, through which the flow was very rapid. In some of the later experiments this accident was avoided by gently compressing the arterial trunk with the finger, reducing thereby to a considerable extent the rate of the flow. On one occasion only did the blood apparently clot in the tube, and that was undoubtedly due to the very small caliber of the tube used. In one other experiment clotting occurred in the vein near the extremity of the tube, due to an accidental separation of the paraffin coating. In one other case the blood did not at first flow through the tube, but the arrest of the circulation was found to be due to a clot in the artery from a wound of the intima due to a too vigorous application of the preliminary clamp. When the injured part of the artery was cut away, blood flowed through the tube as in the other experiments. The authors believe that this is the simplest method proposed; that it can be carried out by any surgeon of ordinary experience without the necessity of previous training. They also believe that considerable time may be saved by its employment, in that it requires a shorter exposure of the vessels than is necessary to effect union when the methods by direct contact are employed. The method has been employed to effect transfusion in a patient at the Roosevelt Hospital, who was suffering from acute anemia due to repeated profuse gastric hemorrhage. In this instance blood flowed for nineteen minutes through a medium sized tube without clotting. The patient rallied well. The hemoglobin rose from 30 to 70 per cent. during the progress of the operation, but he died the following day from a recurrence of the hematemesis.

85. **Inflammatory Conditions of the Alimentary Canal.**—Dolbey suggests that a very close analogy may be drawn between inflammation of the tonsil and other inflammatory conditions of the intestines; that the tonsil is the type on which we found a basis of our understanding of inflammatory conditions of the lymphoid tissue of the alimentary canal. The fact that there is normally no lymphoid tissue in the stomach of the new-born infant, and that gastric lymphoid tissue increases in amount up to middle life, and tends to disappear entirely in the later years of life, gives us an easy, if rather superficial, explanation of the rarity of acute inflammatory ulcerative conditions in children or the aged. The absence of lymph tissue in those individuals above 50 will supply a pathologic basis for the well-known clinical findings in gastric conditions in this age. Thus we obtain pathologic support for the dictum that if a patient develops gastric symptoms for the first time after 50, it is more than probable that we have carcinoma of the stomach to deal with rather than ulceration. The incidence of lymphoid tissue at the pylorus and on the lesser curvature explains why chronic ulcers of the stomach are so much more common in those situations.

90. **Accidental Implantation of Epithelioma.**—The clinical points of interest in Hubbard's case may be summarized as follows: 1. The change of an ulcer of the right forearm, which had been for years simple in character, into an epithelioma of marked malignancy. 2. The breaking down of the tissues after an operation following directly on numerous exposures to the x-ray and radium. Was it ordinary sepsis, or were the tissues so altered that they could not withstand the added irritation of an operation? 3. The direct inoculation of the breast with the epithelioma. 4. The case emphasizes, in general, the importance of removing cancer with an area of healthy tissue about it. It illustrates the possibility of spreading the disease by bringing the cancer in contact, by instruments or otherwise, with the wound.

91. **Rapid Interlocking Suture.**—To make the suture described by Bookman no special instruments are necessary, only several self-threading, calyx-eyed needles and a spool of Pagenstecher celloidin linen thread or plain silk (preferably the former). The needle used had better be of the long, round, half-curved kind which is easier to handle, and the suture material should be wound on a spool in one continuous length of from ten to twelve yards. After the bowel has been resected, the cut ends are caught in traction sutures so that the mesenteric triangle is situated from one-half to three-fourths of an inch inside the left traction suture. When only a few stitches are required and the suture material used is catgut it is better not to use a self-threading needle lest it tear the strand, but to thread a number of needles on the catgut beforehand and slide them along as required. For a detailed description, the original paper should be consulted.

92. **Tube and Valve Device for Expanding Collapsed Lung.**—The device consists of an ordinary soft-rubber drainage tube of any size desired, and a valve made of oiled silk, any

flexible waterproof material or of aluminum; a flexible shield for protecting the valve from interference from the external dressing and to hold the tube in a pivotal manner, thus maintaining it in the chest wall without bending or causing lateral pressure on the tissue. The elastic wing of the shield under body bandage with appropriate pressure, holds the shield in coaptation to the chest, both in inspiration and expiration. A secondary specially devised bandage, over the base of the shield, prevents later movement, hence the combination of the pivotal hanging of the tube, the elastic wing of the shield under appropriate pressure, and the secondary body bandage maintains the tube in absolutely perfect position, leaving the patient free to move as he pleases, in bed or out. The manner of attaching the tube to the shield also prevents the discharge from regaining access to the pleura, as it at once drops away from the end of the tube as soon as it leaves the pleural cavity.

Air is prevented from gaining access to the pleura around the drainage tube by winding the distal end of the tube with 5 per cent iodoform gauze. It does not need to fit the opening overly tight to serve this purpose in practice. As to the valve, in cases of moderate collapse, the tube is used with the end cut at a right angle. This valve closes instantly at the beginning of inspiration, and enables the full atmospheric pressure to act inside the lung. While negative pressure is ordinarily understood, it is not produced within the pleural space by this method. Rarification in sufficient degree is produced to cause rapid expansion of the lung.

102. **Epidemic Meningitis.**—Overton studied records of 17 patients. Of these 3 were untreated, and all died; of the 12 treated, 7 died; but of these 7, 2 were practically moribund at the time of injection, and 1 died in less than twenty-four hours after the first injection. Five recovered, 4 of these by crisis and 1 by lysis. Recovery was complete in all but 1, and this 1 has still internal squint in one eye. Of the treated patients who died, all died within the first week. Of the 17 patients 5 were white and 12 colored. There was one child 2 years old and one 7; there were 3 men over 50, and the other patients were between 10 and 30. There was a history of premonitory symptoms in 3, and history of recent intoxication in 3. The symptoms noted were: Headache, rigidity and tenderness in neck, and Kernig's sign, in all; Babinsky's sign in 4; herpes in 4; internal squint in 2; paralysis of external rectus in 2; haziness of vision in 2; diplopia in 1; irregular pupils in 4; conjunctivitis in 2, and photophobia in 1; facial paralysis in 3; convulsions only in 1, a child of 2 years; chill in 9; vomiting in 4; typical attitude in 2; irrational state of mind from that of mild degree to active delirium, requiring watching and restraint, in all but 1; albumin in urine in 3; retention or incontinence early in all but 4, present before death in all; sweating free in 5; typical rash in 1; and urticarial rash in 1; in 4 emaciation before death was extreme; there was deafness in 2; there were 2 instances of associated cases; 1 case was complicated with pneumonia; 1 was of the subacute form; the pulse in the bad cases was irregular and slow or running; the temperature was not continuous, and was not above 104, except in one case; there was Cheyne-Stokes respiration in 2. In all who died the leucocyte count remained high, and polynuclears were increased in some to as high as 95 per cent. In the patients who recovered, as a rule, the count gradually fell. The fluid was cloudy in all, purulent in most, and in a few so thick that it would hardly run through the needle. The largest amount of fluid withdrawn from any one case was 270 c.c., and the most serum injected was 210 c.c. The usual dose of the serum was 30 c.c., but on several occasions it was 45 c.c. The effect of the serum on the fluid was generally to increase phagocytosis, to decrease number of diplococci, to lessen their viability as shown by cultures, and to cause a clearing of fluid in most cases of recovery after two or three doses. In patients dying the last cultures were negative in all but one. In those recovering the last cultures were negative in all but one, and in this one the growth was very slight.

111. **Constipation and Resection of Colon.**—Sharples reports one case in which he employed successfully the procedure advocated and first described by Lane—resection of the colon with anastomosis between the sigmoid and small intestine.

112. **Ophthalmoplegic Migraine.**—Veasey's patient was perfectly well, except for violent attacks of headache, which began in her fourth year of age, and which had recently become of more frequent occurrence. These attacks always began with violent supraorbital and temporal pain on the left side, lasting for an hour or two, and were always followed by nausea and vomiting. Occasionally the first vomiting relieved the pain, but more frequently the vomiting was followed by violent retching which usually continued until after the child had secured some sleep. Marked photophobia was usually present during the attacks. Following one attack there was observed a squint in the left eye, the latter turning toward the nose and the patient complaining of diplopia. After a week or two the squint disappeared. A few days before Veasey examined the patient she had an unusually violent attack, followed by prolonged vomiting and retching, and on the following day again complained of diplopia. At the time of his examination there was a distinct internal squint of the left eye, due to the almost complete paralysis of the external rectus muscle.

Examination of the eyes showed the vision in each to be 6/9, and the refractive error to be a compound hyperopic astigmatism. Each optic nerve presented the appearance of the so-called pseudo-optic neuritis. In ten days' time the paresis had entirely disappeared and the patient fitted with glasses. Under treatment the migrainous attacks became somewhat less frequent, but in October, 1907, there were three very violent attacks within ten days' time, all on the left side, the last of which was again followed by paresis of the left external rectus muscle. The paresis of the muscle this time lasted three weeks, after which it had entirely disappeared. Shortly after this attack the patient passed from under observation, so that the subsequent history is not known.

1. **Abscess of Brain.**—In this paper are recorded 19 cases of cerebral abscess in association with pulmonary disease which have occurred at the Brompton Hospital for Diseases of the Chest during twenty-two years (1882-1904), and at the London Hospital during ten years (1894-1904). It is interesting that in the enormous number of post-mortem examinations at the London Hospital, considerably over 10,000 in the last ten years, there were only 2 cases of cerebral abscess in association with lung disease (apart from pyemia), 1 following on bronchiectasis and 1 on empyema. The 19 cases of cerebral abscesses occurred in association with the following pulmonary diseases: bronchiectasis, 14 cases; empyema, 3 cases; abscess of lung, 1 case; emphysema and bronchitis, 1 case.

4. **Peau D'Orange in Acute Mammary Carcinoma.**—The name *peau d'orange* is descriptive enough to one who has seen it, but to those who have not noticed the condition it may not convey much impression, for orange skin is very variable and the irregular pitting and puckering of the latter might very well describe the fairly common appearance of the skin in cancer of the breast when it is affected by contraction of a growth underneath. In acute carcinoma, on the other hand, the skin has minute pits occurring very regularly, about a quarter of an inch apart, giving the appearance as if the skin had been jabbed with a blunt pin. The thickening of the skin is due to changes in the corium. These changes are the results of lymphatic permeation and consequent lymph stasis. The corium is expanded and the overlying epithelium is raised above its normal level by the pressure, except at those places where it is bound down by the insertion of a hair follicle deep in the corium, where it is moored, as it were. Taking into consideration the already known cause of pitting in brawny arm and this same explanation advanced for the similar condition, *peau d'orange*, in the breast, it seems reasonable to Leitch to argue that where we get the condition it must be due to lymph stasis caused by blockage of the lymphatics. There is no disease of the breast at all likely to produce this appearance other than cancer. Thus even in the absence of other signs a diagnosis of acute mammary cancer from this alone would practically be certain.

9. **Oral Sepsis with Peculiar Symptoms.**—The patient presented symptoms which strongly suggested quartan malaria, infective endocarditis and Henoch's purpura; but on the extraction of several teeth promptly recovered. A suppurative gingivitis, to which attention was directed by a toothache, was responsible for the entire disturbance.

12. **Facial Paralysis.**—Subsequent to chronic otorrhea, Cunningham's patient developed facial paralysis, first on one side, then on the other, at an interval of almost twelve months. A complete postaural operation on both sides was productive of cure.

13. **Multiple Plexiform Neuroma.**—A female child, aged 5 years and 4 months, presented a swelling of the left side of the neck behind, extending from the left superior curved line of the occiput above, down over the complexus as far as the level of the first dorsal spine below, and extending round in front as far as the anterior border of the left sternomastoid muscle at the middle of its length. Posteriorly, the swelling was limited to the left side of the neck by the ligamentum nuchæ. Soft and semisolid to the touch over the occipital bone, the tumor below was found to consist of firm masses, feeling like glands, ranging in size from a hazel nut to a pea, and more or less bound together by adhesions. The growth was thickest between the posterior border and the upper third of the sternomastoid and the outer border of the complexus. The skin over the entire tumor, with the exception of the occipital part, was stained brown. This stain was most marked over the prominent belly of the complexus, but extended as far as the middle line of the neck in front and also lower than the tumor below, becoming fainter and mottled at the edges. The opposite side of the neck was faintly pigmented. The pigmentation was first definitely noticed at the age of 2 years. (The mother was clear on this point, as friends used to remark that she had omitted to wash the child's neck.) It began at what is now the upper part of the stain behind, and extended slowly downward and forward. It was not until more than a year later that a swelling was noticed to commence beneath the upper part of the pigmented skin. There was no pain, but slight tenderness, which increased, neither had the child suffered in general health. The child had enlarged tonsils, but no other physical signs to aid or complicate diagnosis. The family history was negative. At operation the tumor was seen to consist of lobulated masses of fibrous tissue held together by strands, and almost inextricably mixed up with the muscle fibers. Microscopic sections showed bundles which resembled normal nerve bundles.

18. **Myxosarcoma of Prostate.**—Edington's patient, a boy, was only 1 year and 9 months old. He was admitted to the hospital on account of retention of urine of a few days' duration. The abdomen was swollen generally, but markedly in the hypogastrium. Between the umbilicus and the pubes was a mass. Examination by the rectum showed that the mass occupied the pelvic cavity in front of the bowel. It was firm, resistant and smooth, and the finger could be swept all round it, except anteriorly; it was also tender. There was slight reddening of the glans and foreskin. The left thigh and knee were edematous. At the post-mortem the mass was found to be a myxosarcoma of the prostate.

22. **Madelung's Deformity.**—According to MacLennan, Madelung's subluxation is not a true subluxation, but is a distortion of the joint. It is due to irregularity of growth at the lower radial epiphysis. The radius is curved either outward and backward, or forward and inward (2 cases), giving rise, respectively, to a forward or backward displacement of the hand. It affects both wrists in about 70 per cent. of the cases. It occurs most commonly in females (about 85 per cent.) during the period of most active growth. The deformity is occasionally present at birth. The irregularity at the epiphysis may be due to a variety of causes, such as trauma, rickets or disease of the central nervous system. Such lesions may occur during intrauterine life. The malady is frequently inherited and may be associated with other deformities. Secondary changes occur in the various structures at the wrist after the disease has been present for a long time. The correct treatment is a cuneiform osteotomy when the deformity is fully developed and the epiphyseal line may with advantage be included. The ulnar metaphysis should be destroyed. The slighter cases which could be righted by a simple osteotomy operative treatment is not necessary.

24. **Abdominal Tuberculosis in Children.**—An analysis of 137 cases of well-marked abdominal tuberculosis made by Dingwall-Fordyce shows that the characteristics of this condition are as follows: In a majority of cases the period of the onset of symptoms is prior to the fourth year of life. The disease is of more serious prognosis the earlier in life its incidence, and the earlier its incidence the more acute its nature. When death supervenes it usually does so within eighteen months of the incidence of symptoms, but in a small proportion of cases a fatal issue is much longer deferred. The mortality from this condition among children fed entirely on the bottle (46 per cent.) is higher than among children wholly or partially nursed at the breast for at least three months (28 per cent.). Free fluid in the peritoneal cavity is a relatively uncommon sign in patients under 3 years of age. Only in cases with free fluid in the peritoneal cavity, plus palpable abdominal masses, is an elevated temperature more common than a practically normal one; when free fluid only is detected, marked elevation of temperature is uncommon. The prognosis is most unfavorable in cases with free peritoneal fluid, plus palpable masses (67 per cent. mortality), and it is hardly less so in cases with masses or marked matting (64 per cent.). In cases with free fluid only (29 per cent.) or discrete glands (18 per cent.) the prognosis is much more favorable. A high swinging temperature, whatever the age and whatever the physical signs, is of very small evil omen; a slight elevation of temperature is of more evil omen the younger the child; absence of rise of temperature—whatever the physical signs—is usually associated with a fatal result only in younger children.

25. **New Tuberculin in Surgical Tuberculosis.**—Power's results point to the conclusion that new tuberculin, given by the mouth in small doses, is useful in the slighter cases of surgical tuberculosis. It is often sovereign against the chronic sinuses which are so often formed after operations on tuberculous tissues—troublesome cases in which the wound nearly heals but not quite, and in which it breaks down time after time on the smallest irritation. It is valuable in enlarged cervical glands which have not undergone extensive caseation or suppuration. It has failed in this crude form in Powers' hands to give any relief to patients suffering from tuberculous peritonitis, tuberculous disease of the joints, and from inflammation of the bones due to tuberculous infection.

42. **Etiology of Hernia.**—Sheen discusses injury as a factor in the causation of oblique inguinal hernia, considering the question mainly from the medicolegal standpoint.

45. **Lymphadenoma of Small Intestine.**—A man, aged 30, had suffered from pain in the abdomen for two months, with occasional vomiting. His bowels had not moved for seven days. On examination of the abdomen, a sausage-shaped tumor was found in the right iliac fossa. Its lower, outer and inner edges were sharply defined, but above, toward the right hypochondriac region, the belly muscles were rigid, and the upper edge of the mass could not be determined. The tumor was not absolutely dull. It was rather tender and felt doughy. The abdomen was not distended, and was rigid only over the right side, especially just below the costal margin. By rectum the tumor could be felt by the finger. There were no physical signs of disease elsewhere. An enema was administered and a large quantity of hard feces was evacuated. The tumor did not diminish in size. On the following day the patient vomited, and the pulse became rapid and small. An examination of the blood was made, which showed a slight polymorphonuclear increase. No leucocytosis was noticed. A diagnosis of appendicitis was made and laparotomy performed. The tumor was then found to be a large intussusception; the intussusceptum was gangrenous and the sheath perforated. It was removed and the gut united by end-to-end approximation over a bone tube. The patient died two hours after the operation. The intussusception was found to consist of jejunum. There was a second smaller intussusception in the ileum. The

apex of each intussusceptum was formed by a sessile flattened plaque-like tumor. There were six of these growths in the lower jejunum and four in the upper part of the ileum. The tumor at the apex of the jejunal intussusceptum was the largest. There was one small plaque about 10 inches higher up, and the others were contained in the succeeding 6 feet of intestine. The tumors projected into the lumen of the gut from its mucous surface; their edges were covered by mucosa. The flat surfaces of the plaques were uncovered by mucosa, and the centers of the larger tumors were umbilicated. The growths varied in size from that of a shilling to that of a crown piece. They were oval in shape, their long axes being at right angles to that of the intestine. They were not situated at the mesenteric attachment of the gut, nor directly opposite to it, but were found at the side thereof. Peyer's patches were not enlarged, and there was no enlargement of the mesenteric or of other lymph glands. Microscopically, the plaques were found to consist of lymphoid tissue.

50. Treatment of Quinsy.—Guthrie reports a case to illustrate a method of treatment which has proved successful in his experience. The supratonsillar swelling was opened in the usual way with bistoury and sinus forceps, and a quantity of blood-stained pus evacuated. A tent was erected over the bed, and inhalation of steam with compound tincture of benzoin was given constantly—a measure which afforded the patient much relief—and a calomel purge was administered. Toward evening the swelling had slightly diminished, but swallowing was still impossible and speech thick. Ice was ordered to be sucked at intervals, and instructions given that 2 drams of brandy be administered every three hours as soon as the patient was able to swallow. On the following morning the patient could swallow with little difficulty and the edema had diminished. Temperature was 99; pulse, 85. The tonsil of the opposite side was found to be covered with yellowish spots (follicular condition). A throat spray of peroxid of hydrogen was recommended and the steaming discontinued. A mixture containing 5 minims of liquor strychninæ and 15 minims liquor ferri perchloridi to each (B. P.) dose was prescribed. Following this, the condition rapidly improved, edema and swelling diminished and the patient made an uneventful recovery.

57 *Tuberculosis in Infants. (Tuberculose des nourrissons.) H. Barbier.
58 *Isolation of Contagious Cases in Children's Hospitals. (Isolement des maladies contagieuses dans les hôpitaux d'enfants.) L. Baumel.

57. Tuberculosis in Infants.—Barbier states that whatever the predominating anatomic form of the tuberculosis, atrophy and dyspeptic disturbances are constant, with marked involvement of the liver in the latter and their resistance to the best planned diet. These children are particularly sensitive to dietetic errors, especially the abuse of cows' milk, or there may be anaphylaxis for this. There may be also other general or functional signs, inflammation of the glands, enlargement of the spleen, anemia and fever—the picture is completed by the discovery of a bronchial glandular process or of involvement of the lung, especially frequent on the right side. These atypical forms of tuberculosis, inherited or not, are an overwhelming factor in infant mortality, and, with syphilis, they are the most certain and most frequent cause of atrophy of the viscera, especially of the liver, as also of many deformities of the bones which are generally ascribed to rachitis. He describes the typical and atypical forms, the latter being most frequent in the inherited variety, the nutritional disturbances possibly proving fatal without a single tuberculous lesion discoverable at autopsy. Acquired tuberculosis in infants runs a typical course similar anatomically to that in adults.

58. Isolation of Contagious Diseases in Children's Hospitals.—Baumel describes the favorable experiences at Montpellier with a series of interchangeable, single-bed, isolated rooms on each side of a corridor. At the other end of the corridor are rooms with three or four beds for convalescents; the two series are separated by a corridor at right angles. Around the outside of the pavilion is a broad piazza or terrace on which each room opens with glass or wire-netting doors. It is thus possible for the parents on the piazza to visit with the sick children in the isolated rooms without direct contact, and this humane provision has proved extremely successful. Another point important in prophylaxis is that the children are taken to the isolation rooms without the necessity for passing through other wards. The toilet, disinfecting rooms, dishes, etc., and the attendants of the isolated single rooms are entirely distinct from those of the convalescent rooms—the aim being to prevent contact in any way. The gate admitting to this ward from the street is entirely separate from the general entrance. Another point on which he insists is the necessity of keeping the little patient the entire period required for isolation: 45 days for diphtheria, scarlet fever and smallpox; 25 days for measles, and 15 days for mumps, chicken pox, etc. The schools, clinics, day nurseries, and other public places where children are assembled should not admit a child after an absence of several days until it presents a medical certificate and the required period of isolation for the disease in question has fully elapsed, counting from the beginning of the disease. He presented this article at the international medical congress, urging the adoption of a resolution protesting against any lack of individual hygiene in carrying out these measures of public prophylaxis, citing as an example a case in which a child with measles was called for by a city ambulance and taken out of bed on a winter night. Instead of compelling the patient to get up and dress, he should have been taken on the mattress, which could have been disinfected and returned. The pediatrist can never be too much on the alert, or too precise in his directions to avoid all chance for dangerous contacts; this is more important and more difficult than to disinfect, but it is the only safe prophylaxis.

60. Treatment of Hemorrhoids by Total Circular Excision.—Villard reports 24 cases in which the patients were promptly and permanently cured by the method of which an illustrated description is given. The anus is widely dilated thus bringing the ring of hemorrhoids outside; this ring is excised, the parallel circular incisions being carried along as the varicose strip is dissected. The mucosa is detached in the direction of the circular fibers of the sphincter, thus utilizing the plane of cleavage. The vessels are ligated above and the mucosa is easily sutured over the ring of raw surface left by this excision.

61. **Tetanus of the Head.**—Binet reports a case of cephalic tetanus, symptoms of paralysis and of contracture occurring together. The treatment is the same as for generalized tetanus. The mortality of this form is still 38 per cent. and it is liable at any moment to become transformed into generalized tetanus. The prognosis is graver, the shorter the incubation after the traumatism. Spasm of the glottis may prove fatal and general symptoms may develop as late as the fiftieth day after the first manifestations of the cephalic tetanus. His patient was a young man and the head tetanus developed six days after a contusion of the face. He recovered under bromid, chloral and serotherapy. No attempt was made to cauterize the wound.

62. **Subphrenic Abscess.**—Piquand here concludes his long monograph on this subject which is based on 890 cases in the literature. He discusses the history and details of the various kinds of subphrenic abscesses, classifying them according to their origin, with source, concluding with his own experience. The tuberculous subphrenic abscess is rare and is generally consecutive to tuberculous lesions of adjacent organs. In 7 cases the primary affection was in the liver; in 4 in the kidneys; in 3 the subphrenic peritonitis was the result of a tuberculous intestinal process. No examples were encountered of subphrenic abscess resulting from tuberculosis of the pancreas or spleen, but 3 authors have reported some from pulmonary tuberculosis; tuberculosis of the walls of the chest is a frequent cause of subphrenic abscess. In 5 cases the subphrenic abscess was merely one localization of a diffuse tuberculous peritonitis. In others it is possible that the subphrenic lesion constituted the primary manifestation of tuberculosis. In 31 tuberculous subphrenic abscesses only 8 of the patients recovered. In 17 cases no operation was attempted and all these patients died, while 8 recovered out of 14 operative cases.

63. **Results of Operative Treatment of Megacolon.**—Duval reviews 94 operations on record in treatment of this condition. The mortality was nearly 75 per cent. in 59 cases under medical treatment, while it was 34.2 per cent. in 35 operative cases. Eight different technics were followed in the various cases, and he compares the ultimate outcome with each. Resection of the colon has always given the best results; it is the logical treatment of these segmental lesions of the colon, but even this fails in the cases in which the dilatation recurs in another segment of the intestine, in which case all therapeutic measures are futile. In Richardson's case, the entire large intestine became dilated after three operations.

67. **Gastrointestinal Functional Weakness and Functional Disturbances in Young Children.**—Selter emphasizes the importance of investigating the functioning of the digestive apparatus when children show that they are not thriving. For this, examination of the stools is imperative. He examines some of the stool obtained when the child is first seen, and from the findings in this specimen orders a test diet regulated to exclude the articles which the stool showed were imperfectly digested. Comparison of a specimen of the stool about the third day with that of the first day gives an instructive oversight of gastrointestinal functioning. He gives full details for examination of the feces and interpretation of the findings, especially insufficient mastication; excess of fat; the "carbohydrate stool" with its foamy, acid, fermentation, scraps of potato, etc., and other findings; the "meat stool" showing defective pancreatic or intestinal secretion; the "connective tissue stool," indicating impaired gastric digestion; the "constipation stool" and the catarrhal, and combinations of any of the above. Treatment based on the findings in the feces is generally successful. The aim is merely to arrange the diet so that none of the food escapes digestion, restricting or dropping entirely the substances which the child is transiently or permanently incapable of assimilating. In constipation he has obtained good results with plenty of fat and agar-agar in the form of a pudding or added to milk. The total amount of food should be limited to that strictly necessary. Rest and warmth are the main other factors, letting the child sleep late and take a nap in the day, with thermophore or hot bran cushion for local application of heat for two hours after each meal. Even when the child is up and about, he has the hot cushion worn in a pocket made for it in the waist or shirt. Abdominal massage with a wooden ball (250 gm. in weight) for ten minutes in the morning is a useful adjuvant. In the mild cases a complete cure follows but in others a certain functional weakness may persist for a long time and the diet may require this individual regulation for years to permit the child to develop normally.

69. **Acute Bone and Joint Diseases of Infants.**—Trumpp cites five examples of bacteriogenic and traumatic epiphysitis in infants.

82. **Present Status of Lumbar and Local Anesthesia.**—Bier states that in his last series of 339 cases of spinal anesthesia vomiting occurred in only 5 per cent. and pallor, nausea and brief disturbance in the pulse in only 9 per cent. Headache was noted in 6 per cent., but exclusively in women who were subject to headache. Spinal anesthesia he regards as indicated only when local anesthesia is inadequate and general anesthesia is contraindicated. He adds that the combination with the scopolamin-morphin "twilight sleep" has been applied often with good results in his clinic, although the lumbar anesthesia alone has proved sufficient even for removal of the rectum.

Klapp and Ehrhardt's suggestions have not yet led to unobjectionable results. His method of vein anesthesia, he asserts, has proved its usefulness and enables operations on the limbs to be performed absolutely painlessly. (It was illustrated in The Journal, May 1, page 1466.) The secret of success in ordinary local anesthesia for large operations, he says, lies in waiting for fifteen minutes at least before commencing. He reviews the various methods of local anesthesia, remarking that Braun's subcutaneous perineural injection on the nerve leading to the hernia has supplanted Cushing's method. The "twilight sleep" is sometimes useful as a preliminary to local anesthesia, especially for excited patients with exophthalmic goiter.

96. **Changes in the Circulatory Apparatus with Change of Position.**—Dietlen tabulates the details of 66 cases in which the change in the size of the heart was most striking as the individuals reclined or stood. The normal heart grows smaller as one stands, while the pulse increases. But these changes are not observed in the elderly and in those with heart affections. It is evident that auscultation of the heart may be misleading unless the patient is examined both reclining and standing.

97. **Treatment of Severe Anemia with Transfusion of Small Amounts of Human Blood.**—Weber reports 7 cases from Voit's medical clinic at Giessen in which threatening anemia was influenced to a remarkable extent by transfusion of only 5 c.c. of human blood. No benefit was observed in a number of cases of leucemia. The transfusion of this small amount, he states, is simple and generally harmless, but in a few cases there were signs of mild disturbances after the transfusion. It seems as if the blood from certain persons displayed more toxicity than from others, three patients injected with a certain blood all presenting the same transient disturbances. It was never noticed that when two or more patients received blood from the same source, that one presented disturbances and the other did not.

104 Radical Operation for Inguinal Hernia. (Zur Radikaloperation der Leistenhernien nach Kocher.) K. Hugel.

99. **Autoinfection in Obstetrics.**—Krönig applies the term "autogenic infection" to that resulting from the bacteria physiologically present in the vagina and vulva, not brought by the obstetrician or nurse. His experience indicates that fully half of the cases of infection soon after delivery are due to aseptic or saprophytic infection of the endometrium; a very small proportion to infection of deep lacerations, and the others are due to extragenital causes. Comparison of the cases in these categories shows that as a rule the septic puerperal affection of autogenic infection runs a mild and brief course. When it is severe there is generally some special local or general predisposition. During a protracted birth the tissues may be so injured that severe infection may result, even when of autogenic origin. With transverse presentation or contracted pelvis if aid is not rendered artificially, the woman may succumb to sepsis from the autogenic infection. He ascribes the difference between the course of autogenic and exogenic infection to the difference in the virulence of the germs. Those physiologically present have been leading a saprophytic existence and their virulence has become attenuated. In exogenic infection the germs brought have generally been living as parasites in some infectious focus and this parasitic existence has enhanced their virulence. He denounces any attempt to disinfect the vagina and vulva as sure to interfere with the physiologic local defensive processes.

101. **Hypophyseal Tumors.**—Bychowski reports a case of tumor in which the bitemporal hemianopsia, the adipose and congenital dystrophy and the abnormal shadow cast by the sella turcica confirmed the assumption of a tumor of the hypophysis. The patient was a young woman and the first symptoms were impaired vision, headache and uncontrollable vomiting. Seven illustrations are given of the findings before and after removal of the tumor by way of the nose. It proved to be a cyst containing two teaspoonfuls of a brown fluid. Recovery was delayed by acute transient meningitis, but the patient was dismissed in two months and a half, entirely free from symptoms, vision 2/3 and 1/10. In all the cases on record the immediate subsidence of the apathetic depression was marked and this was also observed in the present case. The hemianopsia develops first in one eye, which aids in differentiating a tumor in the hypophysis. The development of the genital organs is also liable to be defective with hypophysis tumors, while with tumors of the pineal gland the sexual organs show a tendency to premature development. In Marburg's case the menses dated from the age of eight. Bychowski reviews the experiences of others with hypophyseal tumors and urges prompt operation as soon as the diagnosis is established.

102. **Tubercle Bacilli in the Blood.**—Schnitter has found the Stäubli technic useful for determining the presence of tubercle bacilli in the blood, and tabulates the findings in 34 cases. They were positive in 50 per cent. of 4 cases of tuberculosis outside of the lungs; in none of the 8 cases of pulmonary tuberculosis in the first stage; in 22 per cent. of 9 cases of the second stage, and in 47 per cent. of 17 cases of advanced tuberculosis. Stäubli's method was described in The Journal, Jan. 30, 1909, p. 426. He dissolves the red corpuscles of the blood by adding 10 or 15 times the amount of 3 per cent. acetic acid and then centrifugating. Schnitter obtains the blood by venesection, adds twice the amount of the 3 per cent. acetic acid solution and then centrifugates.

107. Epigastric Hernia Without Palpable Tumor.—Mohr has had two cases of this kind in the last few years and describes the difficulty in diagnosing the true cause of the stomach disturbances which were long ascribed to nervous dyspepsia, gastric ulcer, gall-stones or neurasthenia. The patients were men of 34 and 40 and one had had two previous operations performed for supposed abdominal hernia, but the pains soon returned. They seemed to radiate from a certain spot behind the old cicatrix, and at this point the omentum had been drawn out into a peak, the tip of which had grown to the abdominal wall in one case without actual hernia. This peak was resected and the patients' disturbances were cured. The diagnosis is suggested by the history of the disturbances and exacerbation of the pain with certain movements, bending over, sneezing, etc. Stomach disturbances with localized tenderness in the median line should always suggest hernia in men whose occupation requires rapid bending and stretching of the trunk or lifting weights. These repeated traumatic injuries predispose to hernia but are seldom heard of in connection with true stomach affections. It is difficult to distinguish between an epigastric hernia and gastric ulcer, but the lack of connection of the pain with the taking of food, the unimpaired appetite during the intervals of freedom from pain, speak in favor of the former as also the localized center for the radiating colicky pains, the aggravation of the disturbances by physical effort, and their subsidence on reclining. The hernia occurs most often in hard-working men while gastric ulcer is most frequent in anemic girls. An exploratory laparotomy is indicated on suspicion of hernia with severe disturbances, and the prompt cure of the trouble by the operation confirms the diagnosis even if no actual hernia is discovered.

112. Gangrene After Local Anesthesia.—In the first of the two cases reported, the great toe became gangrenous four days after an operation under local anesthesia for an ingrowing nail. In the other case a hydrocele was operated on under novocain-adrenalin and gangrene of the scrotum developed. Both patients were elderly and there was a suspicion of arteriosclerosis. The salt solution used was unusually strong, owing to a mistake, and experiments with this solution showed that the addition of the adrenalin favored the production of gangrene. Strohe warns that the salt solution should never be stronger than 0.9 per cent., approximately the same osmotic tension as that of the blood.

116. Operative Stomach Disease.—Rondorf expatiates on the advantages of an exploratory operation in obscure gastric affections and relates the good results of operation in 5 cases of gastric ulcer, 7 of gastroptosis or gastrectasia, and 2 of inoperable carcinoma treated by anterior gastrostomy. His experience shows that an apparently inoperable tumor may prove to be operable when exposed, while some which seem to be insignificant are found inoperable. Radical resection is preferable to gastroenterostomy for cancer of the pylorus, he thinks, as this gives a chance for permanent cure while with gastrostomy the patients are still tormented with pains. Resection is indicated, he declares, whenever no metastases can be discovered elsewhere. The size and extent of the tumor are no contraindication, but the operation should not be deferred, even if the patient seems to be doing well under internal measures, until he becomes too debilitated for successful intervention. The surgeon should not hesitate to operate even in advanced and apparently desperate cases, as he can do much good with extensive resection; gastrostomy alone is merely a kind of protracted euthanasia.

120. Nephropexy.—Sonnenschein describes the technic which Bardenheuer has been applying during the last ten years with good results. Seven of the twenty patients thus treated have been under observation for three years or more and the kidney still maintains its normal position with the cure of the previous disturbances. He aims to fasten the kidney as high up as possible, making an ample recess for it, and fastening it there by the adhesions that result when the adipose and fibrous capsules have been slit over the convexity of the kidney and drawn together again. Granulation is stimulated by a tampon below and the whole is strengthened by a muscular support made from the half of the quadratus lumborum which is turned over upward and on which the lower pole of the kidney rests. An important factor in the complete cure is the strict bed rest imposed for six weeks.

125. Importance of Castration in Treatment of Mammary Carcinoma.—Cahen has applied this measure in 7 cases of mammary carcinoma as he relates in detail. In the first case a woman of 27 had noticed a hardening of the right breast for a year before it was removed with the enlarged adjoining glands. A month later castration was done, after which the enlarged glands in the axilla subsided spontaneously to normal size and the patient gained 22 pounds in weight and a robust appearance, but succumbed to a recurrence by the end of the year. The results of the castration were equally marked in two other cases and the patients are still in good general health to all appearances, although excision of a recurring nodule was required in these cases. All these patients were young women with extensive cancers. He urges experimental research to determine the influence of castration on mammary cancers. The carcinoma in the breast in all his cases was differentiated with the microscope, and his experience to date has convinced him that castration should be regarded with favor as an adjuvant to local operative measures for mammary carcinoma in young women. Survival of the patient for three and a half and over five years to date in some of the cases seems to confirm this.

135. Stenosis of the Pylorus in Infants.—Pfaundler presents 57 pages of evidence to show that the clinical signs of stenosis of the pylorus may occur both with and without an actual organic basis.

136. Concentration of the Blood in Infants.—Reiss gives the details of twenty-one cases, mostly of gastrointestinal disturbances in infants, to illustrate the assumption that the severe syndrome in gastrointestinal catarrh in infants is in large part due to the loss of fluids in the diarrhea and, in consequence, the suffering of the tissues from the lack of water. This may be severe while yet the child shows no direct signs indicating the source of the trouble. The somnolency and convulsions, etc., in acute gastroenteritis are mainly due, he thinks, to the abnormal concentration of the blood and other organic fluids. The only reliable means of determining the actual concentration of the blood is with the refractometer. This reveals the condition without fail even when the freezing-point of the blood proves a misleading guide owing to the constant tendency of the organism to maintain its molecular concentration. In many cases in which refractometric examination showed extreme concentration of the blood, the freezing-point was approximately normal.

143 *Treatment of Spastic Paralysis by Resection of Posterior Spinal Nerve Roots. (Behandlung spastischer Lähmungen mittels Resektion hinterer Rückenmarkswurzeln.) O. Foerster. (Die Technik der Foersterschen Operation.) A. Tietze.

138. **Gastric Sarcoma.**—In this communication from Breslau 3 cases are reported in detail and compared with 146 collected from international literature which are tabulated in 14 groups. Operative treatment was applied in 52 cases and the ultimate outcome was about the same as with carcinoma. The course of a gastric sarcoma seems to be rather shorter than that of a carcinoma, averaging not over 17 months and still less for the spindle-celled and round-celled varieties, although for the less malignant myosarcoma it averages 3 years and 4 months. The tables and bibliography include 3 cases published in THE JOURNAL (Baldy, Dock and Howard), 1898-1902.

139. **The Cammidge Pancreas Reaction.**—Schmidt applied this test in 14 cases of gastric cancer or pancreatitis, the findings in some having the value of an actual experiment on account of the pancreas having been injured in operating on other organs. In addition to this he conducted research on cats and dogs and gives the details of 29 different series of tests. His conclusions emphasize the importance of this test, although his research has shown that the reaction is not specific for pancreatic affections, but occurs as the result of destruction of substances with nucleoglycoproteid content. The pancreas being richest in pentoses gives the reaction the most readily, but it may be observed also in other affections accompanied by considerable destruction of tissue and especially of nuclei. A single negative response should not be regarded as conclusive, and a positive response does not indicate exclusively a pancreatic affection. But as those affections which are also liable to give a positive reaction (pneumonia, appendicitis with diffuse peritonitis) are generally so readily differentiated from pancreatic disease there need be little confusion on this account. A positive response with suspicion of a pancreatic disorder is strong corroborative evidence. (The technic for the Cammidge pancreatic reaction was published in THE JOURNAL, Aug. 22, 1908, page 691.)

142. **Appendicitic Symptoms in Incipient Pneumonia.**—Melchior differentiates the condition by the incongruence between the slight objective signs in the region of the appendix in comparison to the intensity of the general malaise, the high fever, spontaneous pain in the chest, headache, flushed face, rapid breathing and relatively good pulse. A little cough confirms the diagnosis of pneumonia even before any physical signs in the lungs can be detected. Herpes and a preceding chill are additional evidence. He discusses further the differentiation of typhoid commencing with symptoms simulating appendicitis. A number of persons have been operated on by mistake on this account. Both typhoid and pneumonia are accompanied by prodromal discomfort, headache and slight heaviness. Dicrotism is the rule in the typhoid pulse which is relatively low, an important differentiating sign in comparison with the full, high pulse of pneumonia. The number of leucocytes is also abnormally low in typhoid in comparison to the hyperleucocytosis of pneumonia and appendicitis. Melchior does not ascribe any special prognosis to the pneumonia commencing with abdominal symptoms. In the 10 cases on record in which the appendix was operated on by mistake, only 2 of the patients died, showing the tolerance of pneumonia patients for a laparotomy. In more than half of the cases on record the rapid breathing attracted attention from the first even before the pneumonia was differentiated. The respirations increase in frequency outside of affections of the respiratory apparatus only with severe generalized peritonitis or when the diaphragm is pushed up by tympanites or effusions. An initial chill was observed in only 4 of the cases. In some on record the onset was sudden and acute; one patient collapsed on the street and was operated on at once on suspicion of perforated gastric ulcer. The prodromal discomfort which is the rule with pneumonia is seldom observed with appendicitis; here the symptoms are generally limited to the abdomen. Vomiting was a frequent early symptom in these pneumonia cases; some of the adult patients vomited several times during the first few days—a rare occurrence with pneumonia in adults, although common in children.

143. **Treatment of Spastic Paralysis by Resection of Posterior Spinal Nerve Roots.**—Foerster here presents a monograph on the causes of spastic paralysis and effects of operative treatment by resection of three or four of the posterior roots. He reports with illustrations two cases of congenital spastic paralysis of both legs with slight paresis of the arms, a case of tuberculous cervical spondylitis and another of multiple sclerosis, both with total spastic paraplegia of the legs and one of right hemiplegia, in all of which he tried this method of operative relief. In the first three cases the spastic contraction of the muscles was materially improved or entirely remedied. The results were pronounced even directly after the operation, the exaggerated reflexes being reduced to normal with cessation of the reflex movements associated with the voluntary movements. By severing the roots it was seen that the corticogenic excitability of the different muscles was still retained, so that volitional movements then became possible. After the operation the patients must be trained to use their limbs properly and they must be controlled with orthopedic appliances to prevent the limbs from assuming abnormal positions until volitional control is fully regained. The last two cases are instructive from several points of view; they show among other things that this method of operative treatment is less promising for the arms than for the legs, while it offers an encouraging outlook for severe spastic paralysis of the legs of either spinal or cerebral origin. For the present he operates only in cases in which there is nothing to lose, although he does not forget that in exceptional cases Little's disease has been known to improve spontaneously. Compression myelitis, multiple sclerosis, etc., also justify this measure, but he does not advise it in cases of mere hemiplegia except for a hemiplegic arm with pronounced spasmodic contraction and reflex comovements, especially in cases of infantile hemiplegia in which the spastic trouble is pronounced while the paretic is comparatively slight. Such cases are particularly promising. No sensory disturbances were noted in his patients after the operation nor decided ataxia, except that in one instance a pre-existing ataxia persisted to some extent. The technic is described by Tietze in detail; it does not differ essentially from any laminectomy, but is best done at two sittings. He commends the intervention as a great onward stride in the treatment of spastic paralysis. It does not restore normal conditions, but it is surprising to behold how the theoretical premises are confirmed by the effect of the operation. It is remarkable to see how a child previously entirely helpless, unable to take a step, can be put on his feet and enabled to walk after a fashion, without any direct surgical intervention on his legs. The success attained is due in large measure, Tietze declares, to Foerster's patience and perseverance in training the patients afterward to use their limbs. In one case a secondary local operation for contracture was necessary. The illustrations "before and after" show the previously helpless child now walking upstairs.

146 Significance of Glandular Hyperplasia and Hypertrophy of the Endometrium. K. Himmelheber.

144. **Transverse Presentation, Version and Extraction.**—A recent German article stated that about 2,000 children and 400 mothers lost their lives annually in Germany in consequence of transverse presentation, and these figures were denounced as excessive. Schultze here presents detailed statistics which show that the number is actually twice as high, fully 4,000 children not surviving birth on this account. Few succumb to the transverse presentation itself; the trouble is in the extraction by the foot before dilatation is complete. He urges that if the cervix is not sufficiently dilated, operative delivery by some method of Cesarean section should be given the preference. Version does not avert the danger that threatens the child, and extraction is dangerous both for mother and child. By waiting until the os is completely dilated, if the transverse presentation of the child is the only indication for version, and by patiently waiting for spontaneous foot delivery, so long as there are no indications for immediate extraction, he is positive that many of the 4,000 children who now die during delivery from transverse presentation would certainly survive. He adds that no attempt should be made to loosen the cord as this is entirely unnecessary and liable to harm the child.

149. **The Senile Type of Epidemic Meningitis.**—Reiche's experience in 2 cases confirms Schlesinger's statement, based on 5 cases, that epidemic cerebrospinal meningitis runs a peculiar course in the elderly, affecting a senile type. The Kernig symptom was always pronounced, but there was slight or no opisthotonos. The latter may also be absent in cases in children under three. There was little tendency to fever in these elderly patients; in some the temperature never rose above normal. The importance of differentiating meningitis is evident not only on account of prophylaxis for others, but also on account of the prompt benefit liable to follow intraspinal injections of a curative serum. In 1 of the cases hemiplegia was almost the first symptom to call attention to the disease, and Schlesinger has reported a case in which the onset of the meningitis simulated apoplexy. One patient was a man of 61 who had fallen down-stairs and the meningitis developed after the trauma, but was not discovered until autopsy. Leyden and others have reported trauma and contusion as the exciting cause of epidemic meningitis during an epidemic. In this sporadic case, however, there must have been some intermediation of a "meningococcus-carrier." There was no herpes in either case.

171. **Eclampsia in New-Born Infants.**—Esch discusses the condition of children born to women in eclampsia, stating that in many cases on record the organs showed the same characteristic changes as those of the mother. Convulsions in the new-born can be ascribed to eclampsia only after exclusion of all other causes, intracranial hemorrhage, intoxication from morphin previously taken by the mother, etc. He has encountered 3 cases in which both the mother and infant presented the typical syndrome of eclampsia. This brings the number on record in accessible literature to 32, except that in 6 cases the mothers presented albuminuria alone, without actual eclampsia. The first convulsion occurred in the infants from a few minutes to forty-six hours after birth, and the convulsions lasted from thirty seconds to ten minutes. The intensity of the convulsions did not seem to parallel the severity of the eclampsia in the mothers, the opposite being rather the case. The infants were all at or near term, but the mortality of children of women with eclampsia is generally high; it was 22.7 per cent. in 234 cases in his own experience. Treatment of eclampsia in the new-born can be only symptomatic, avoiding irritation from without, giving small doses of bromid or chloral by the rectum, with saline-infusion and fluids to promote diuresis, and warm baths to aid in the elimination of toxins.

175. **Permanent Cure of Cervix Carcinoma.**—Reinecke calls attention to the fact that the recurrences in his experience were almost always in women who had had severe hemorrhage or prolonged suppuration during or after the operation. Out of 399 patients only 153 were in an operable condition, and recurrence followed in 76, while 42 have been completely cured for from five to seventeen years. All the recurrences developed within three years.

177 *Search for Perforated Gastric Ulcer. (Ueber die Aufsuchung des durchgebrochenen Magengeschwürs.) C. Ewald.

177. **Search for the Perforation of Gastric Ulcer.**—Ewald states that the perforation is almost invariably located close to the pylorus, above or below, so that it is almost always found inside an area of about 2 square inches, and this region is readily reached by lifting up the margin of the liver concealing it. The easiest mode of access he has found to be by an incision, not through the epigastric line, but parallel to it, through the right rectus muscle, pushing the longitudinal ligament toward the center. The finger is then introduced and as it pushes the longitudinal ligament toward the median line the peritoneum is incised under the guidance of the finger. The margin of the left lobe of the liver is then lifted up and the perforation generally presents; it is unnecessary to draw out the stomach in the search. Only in the rarest cases will the perforation be found elsewhere. He adds that his patients were almost all men between 30 and 50, mostly drinkers, but the few women formed no exception to this rule.

178. **To Facilitate Major Obstetric Operations by the General Practitioner.**—Sellheim urges that every general practitioner should see to it that there is some place arranged for aseptic obstetric operations, easy of access, in the neighborhood, where he can send and operate on his patients without wasting time and effort trying to transform an ordinary bedroom into an aseptic operating room. He declares that even the smallest hospital should have an aseptic maternity room; the surgeons have shown how to conquer all such obstacles. Obstetricians should profit by their initiative, and students should be trained in obstetric operations, from the smallest to the most serious. He insists that all physicians could do a certain share of such surgical work if only they had enough energy. What is right and proper for surgery is right and proper also for obstetrics. It is much wiser, he adds, to teach students every branch of practical obstetrics than to sit with folded hands and watch the present ever-widening separation of School and Practice, which will have to be corrected later.

187. **Indications for Nitroglycerin.**—Dmitrenko reports 23 cases in which he studied the pharmacodynamics of nitroglycerin; its action was manifested in 16 of the cases by subsidence of the pressure in the brachial artery, while at the same time the pressure rose in the arteries in the fingers. This with other facts observed indicates, he thinks, that the drug has an elective action on the peripheral portion of the circulation. As it dilates the arterioles the resistance they previously offered to the blood stream is reduced and thus the work of the heart is lightened to that extent. If the heart is very weak and close to exhaustion the blood pressure in the finger arteries rises very little if at all. The organism responds to dilatation of the cutaneous vessels with contraction of the visceral vessels as the vasomotor innervation strives to maintain the pressure uniform throughout. The power of dilatation of the peripheral vessels determines the amount of action of the nitroglycerin. When the peripheral vessels have lost their elasticity under the influence of typhoid, tuberculous or diphtheria toxins, nitroglycerin is not only useless, but, if the heart is weak, actually dangerous. Under favorable conditions it reduces the pressure in the central portions of the circulation and increases the pressure in the peripheral, the latter feeling the effect longer. It begins to wane in from three to thirty-five minutes, but the action of the drug is still perceptible in the finger arteries by the end of the hour. It is indicated only in the cases in which the pressure at the periphery rises, while the brachial pressure drops under its influence. This phenomenon is particularly evident when the patients feel worse after administration of digitalis, which has whipped up the irritated, much hypertrophied heart muscle without removing the obstacles in the periphery.

Books Received

A METHOD OF COMPLETE NEPHROURETERECTOMY IN WOMEN *

J. WESLEY BOVÉE, M.D.
Professor Gynecology, George Washington University
WASHINGTON, D. C.

Removal of the kidney and ureter simultaneously is closely associated with nephrectomy, an operation first planned and successfully performed by Simon, in 1869. I have failed to find by frequent surveys of the literature of this subject during the past ten years any records of nephroureterectomies that necessitate alterations in the tables and case references contained in my paper read before the Southern Surgical and Gynecological Association in 1899.[1] This table credited H. A. Kelly, of Baltimore, with performing the first nephroureterectomy, Dec. 18, 1895, for tuberculous ureter. During the following month the late A. J. McCosh, of New York, performed the operation for tuberculosis of the kidney.

ROUTES

Early in the history of this operation the two principal routes employed were the loin extraperitoneal and the transperitoneal. The greater danger of infection that frequently attends the transperitoneal route would reasonably prevent its selection. In 1901 I collected reports of fourteen cases for a paper read that year.[2] Three cases were added to these, making seventeen in all, in my paper of 1903.[3] Seven of the operations had been performed by the loin extraperitoneal, five by that route plus the vaginal and five by the transperitoneal. Kelly, Noble, Montgomery, Ill and myself have recommended the loin extraperitoneal and the vaginal, but no two recommended the same technic.

I shall not discuss the indications for removal of the lower end of the ureter, for they are probably familiar to all. In many cases exsection of the vesical portion will not be necessary, and in some even ligation of the stump of the duct next the bladder wall will not be necessary. But for dealing with the lower two inches of it, particularly for its removal in women, the vaginal incision offers the greatest facility except, possibly, in the virgin. Most operators employing these two combined routes have begun with the renal end by an incision through the tissues down to the ureter parallel to that duct, and making the vaginal incision late in the procedure.

Montgomery[4] made the vaginal opening first, having in view ligation and division of the lower end of the ureter and facilitating upward removal of the lower end by traction, but he abandoned the attempt and proceeded from the loin. Another modification made by him was the employment of the transverse loin incision of König.

Ill[5] removed the kidney through a loin incision, dissecting the ureter well down, and made a second incision in the semilunar line, just above the pubes. Through the latter the peritoneum was pushed back until the iliac vessels were reached, continuing the dissection of the ureter to the iliac artery. He then tied the uterine artery in front of his finger and the internal iliac artery behind it, opening the vagina along the line of the ureter, which was completely loosened. The ureter was finally ligated and severed and the lower part drawn into the vagina, where it was ligated next the bladder and removed.

G. H. Noble[6] removed the kidney and ureter in one piece, separating the kidney and upper portion of the ureter through the loin incision, and after separating the lower portion through a vaginal incision pulled it upward and out through the loin wound. Nov. 24, 1897, Garceau[7] did a ureterectomy, a month after a nephrectomy, in which he loosened the ureter to the broad ligament from above and then through a vaginal incision pulled the duct, severing its attachments and removing it after ligation.

Nov. 7, 1902,[3] in doing a complete nephroureterectomy, I began it by making an incision through the anterior vaginal wall to the ureter, which structure was loosened to its entrance into the broad ligament posteriorly, ligated next to the bladder and severed. Then through the usual loin incision, five inches in length in this instance, the kidney and ureter were separated and removed. In reporting this case[3] on page 320, I referred to the vaginal route being first used, as follows: "This plan I had believed to be best, and when I saw Montgomery do it, although he failed to ligate the bladder end of the ureter, I was convinced." I also recommended the König incision.

TECHNIC

I then adopted the following technic, which has been employed in each instance. Below appears the histories of four cases operated on by it.

The patient is put on the operating-table in the Simon position and the loin area prepared for operation. The preparation of the perineum, vulva, pubes and vagina as for any vaginal operation is now made. The anterior vaginal wall is next exposed and a vulsellum grasps and pulls the cervix downward and toward the introitus to locate the interureteric ligament. On the vaginal wall, exactly opposite the ureterovesical junction, will now be seen a small dimple. From the outer side of this dimple an incision is made downward and outward along the course of the ureter. It should be from one to one and a half inches in length. By careful blunt dissection the ureter is easily exposed and hooked down. If it be considerably enlarged, as it commonly is in tuberculous cases, this procedure is very easy. A metal hook or a piece of suture material is passed around it, and gentle traction made on it facilitates its liberation through the broad ligament. If it is very large, one-half to three-fourths of an inch in diameter, it may be advisable either to ligate or to clamp and sever it, after which it becomes more mobile and can be moved far outward to facilitate its liberation. If exsection from the bladder be thought desirable it may now be done, one layer of sutures being placed first, and the second, if deemed necessary, after the exsection is made and the first layer of sutures tied. A ligature is now placed on the free end of the ureter if a clamp was used.

Cicatrix two weeks after operation.

The patient is next changed to the supine position, and opposite the lower pole of the affected kidney a transverse (König) incision four inches or longer is made through the extraperitoneal portion of the abdominal wall. Its inner end need not be inside the semilunar line. The kidney is now liberated and brought out through this incision and its vessels clamped or tied either before or after it is brought out. By gentle traction on the kidney the fingers are assisted in separating from surrounding structures the ureter to the pelvis, and it is pulled out of the wound with surprising rapidity and facility. If careful dissection has not been accompanied by escape of pus from the kidney or ureter or from a perinephritic abscess, little attention to drainage will be necessary. In my cases I have in two instances felt compelled to employ both loin and vaginal drainage. In the others a piece of gauze has been pushed, by means of a uterine sound, downward along the ureteral tract through the vagina and the vulva, only a strip being left in the abdominal portion of the cavity created by the operation. The loin wound in such cases was completely closed by buried animal sutures. The illustration shows the appearance of the cicatrix when the dressings were removed two weeks after operation. The gauze protruding from the vagina is usually removed fractionally by daily pulling it down after the second day. If loin drainage is used it is preferable frequently to employ the stab wound space for it and close the König incision entirely.

This plan markedly reduces the duration and traumatism of the operation, two points of great consideration in very delicate patients. It facilitates to a remarkable extent liberation of the lower portion of the ureter, provides simple and dependent drainage, permits removal of the kidney and ureter in one piece; allows closure of the wound, except when much pus is spilled; does not exhaust the patient by changing her position during the operation—often a waste of time—and simplifies the preparation of the patient for operation. It does not require any special apparatus for detection of the lower end of the ureter or for its exposure and liberation, although Hawkes[8] considers catheterization of the affected ureter an important preliminary step. The loin incision usually heals promptly and with a small cicatrix.

REPORT OF CASES

Case 1.—*Patient.*—Mrs. B., white, aged 31, primipara, was referred to me by Dr. I. F. Watkins, of Montgomery, Ala. Patient had been ill nearly two years; during this time she had suffered with an unbearable burning and aching sensation over the area of both kidneys, over the bladder and along the course of the right ureter; she had had chills, fever, night sweats and had lost considerable weight.

Examination.—An *x*-ray examination was made by Dr. Ervin, no evidence of the presence of calculi being found. She was then sent to Columbia Hospital for Women, and on July 8 an examination was made under anesthesia. The right kidney was found to be below the ribs and enlarged to one and a half times the normal size. The lower three inches of the right ureter was enlarged and nodular; the left kidney and ureter seemed to be normal in size and position. Segregation of urine by means of Harris' segregator showed tubercle bacilli of the right side, the bladder was much thickened and the urine contained pus and blood.

Operation.—On July 12, 1907, nephroureterectomy was performed. Through a vaginal incision in the right broad ligament the ureter was ligated close to the bladder and separated from that viscus and broad ligament. The abdominal incision, about four inches in length, was made transversely about two inches below the last rib and included about one inch of the anterior margin of the quadratus muscle. After isolating the kidney and the remaining portion of the ureter from above these structures were removed through the abdominal incision in one piece. The peritoneum was accidentally opened at one point not more than one-tenth of an inch in diameter, which was closed with catgut suture. With the exception of a piece of gauze running through the vulva and vagina into the broad ligament opening, no drainage was used. The right kidney was enlarged and contained a number of pockets in which was flaky and cloudy urine; the enlargement of the kidney was found to be not more than 25 to 50 per cent.; the right ureter was enlarged in some places more than others. This enlargement existed close to the bladder and one inch below the pelvis of the kidney. A slight enlargement of the vesical portion of the left ureter was noticed.

Recovery.

Case 2.—*Patient.*—Mrs. H. B., white, aged 41, had one brother who died from an unknown cause; her father died forty years ago of pulmonary tuberculosis. She has a son aged 3 with suppurating cervical glands, believed by her family physician to be tuberculous. She suffered from an abscess of the breast just after her eighth and last confinement, in February, 1907. This abscess had to be lanced several times and required four months for its cure, during which time she had chills and fever. In the following August she suffered from pain in the bladder and frequent micturition, noticing several times slight discoloration of the urine with blood. December 12 pain in the bladder was severe and she expelled from it several ounces of pus with entire relief. In January, 1908, and each month afterward, she suffered a similar attack. Frequently after August, 1907, she had noticed blood but not pus in the urine. Early in October, 1908, she suffered from another attack of chills and fever and noticed a swelling in the left side of the abdomen, and that while lying on the bedpan and pressing on the swelling pus would escape from the bladder with the urine. The patient thought that she had lost fifty pounds in weight since the birth of her child.

---

[8] Hawkes, E. Z.: A Method of Complete Nephroureterectomy for Renal Tuberculosis in Women, The Journal A. M. A., Aug. 8, 1908, li, 459.

Examination.—This revealed an enlargement about six inches in length in its longest diameter in the region of the kidney and, extending from it to the bladder, the ureter was enlarged to about one and a half inches in diameter throughout its entire course. The bladder wall was much thickened. Urinalysis showed a large amount of pus, which on segregation, was limited to the affected side. Several bacteriologic examinations failed to demonstrate the presence of tubercle bacilli. Nevertheless, the diagnosis of tuberculosis of the left kidney, ureter and bladder was made.

Operation.—On Nov. 6, 1908, the kidney and ureter of the left side were removed by the method already mentioned. Longitudinal incision of the kidney after its removal showed at least ten pockets filled with thick blue pus; the ureter contained pus of the same appearance. Two sections of the kidney were examined by the pathologist who reported negatively as to tuberculosis both as to tissue and contained pus. He considered it a picture of pyelonephritic abscess formation and purulent infiltration.

The patient made a very good recovery.

CASE 3.—*Patient.*—Mrs. A., aged 25, Russian, secundipara, admitted to Columbia Hospital for Women, Dec. 3, 1907, for pain in the right side and irritability of the bladder. She had passed bloody urine and had missed three menstrual periods.

Examination.—A cystoscopic examination found the bladder mucosa markedly reddened, the bladder wall thickened, both ureters palpable through the vagina, the right being the size of a lead pencil and hard and the left smaller and not so distinct. Through the abdominal wall the right could be felt all the way to the kidney, the left was not traceable in this manner. A mass was felt in the region of the right kidney of about twice the size of that organ, as the uterus was considerably enlarged pregnancy was diagnosed, she was kept under observation until Jan. 11, 1908, when she left the hospital to which she returned at the time of the birth of her child, May 15.

She was readmitted to the hospital Oct. 20, 1908, suffering with pain in her right side, in the bladder and frequent and painful micturition. The abdominal mass had now increased to a size in excess of that of the head of a new-born infant.

Operation.—Examinations in this instance were negative as to tuberculosis, and on November 10, 1908, complete nephoureterectomy was done by the method described in this paper. The right kidney, about 10 inches in length and about 12 inches in transverse circumference, contained many separate abscesses beside purulent inflammation of the calyces and pelvis of the kidney. The pus was very thick, and in some instances granules of a pale blue color were noted. No calculi were found. The ureter was 1/2 to 3/4 inches in diameter, though having but little more than usual measurements at the lower end and one inch in diameter at the upper end. The transverse incision was directly opposite the umbilicus and about six inches in length.

Recovery.

CASE 4.—*Patient.*—M. B., aged 29, colored, multipara, was admitted to Columbia Hospital for Women, Jan. 4, 1909. She was suffering from frequent micturition attended by pain at the beginning and ending of the act, which had existed nine months. Blood had usually been noticed in the urine during the past month.

Examination.—The left kidney and ureter were slightly enlarged, the bladder thickened and inflamed and tubercle bacilli were found in the urine from that side. The daily quantity was 705 c.c.

Operation.—Jan. 19, 1909, nephroureterectomy was performed by loin extraperitoneal and vaginal routes. The peritoneum was opened for a half inch accidentally and inspected near the opening. It appeared normal and the wound was at once closed. A thickened and nodular ureter and a pyonephrotic kidney were removed in one mass and without leakage.

The patient gradually failed and died March 1, 1909. At an incomplete necropsy next day the following points were noted.

Postmortem Examination.—The parietal and visceral peritoneum were generally and thickly studded with small, white, pinhead-sized tubercles which were most numerous around the area from which the kidney had been removed and the adjacent coils of intestine. Adhesions were rather numerous and firm. A small quantity of yellow pus was present in the pouch of Douglas. The right kidney, small, soft, and somewhat injected, appeared to have undergone some parenchymatous degeneration, but there were no gross lesions of tuberculosis. The walls of the ureter were not thickened. The bladder wall was thickened and the interior studded with older tubercles and ulcers. The lungs, liver, heart and spleen were all pale, soft and bloodless, in harmony with the emaciation presented.

The Rochambeau.

CARDIAC THROMBOSIS

THE CLINICAL AND PATHOLOGIC FINDINGS IN THREE CASES *

FRANK SMITHIES, M.D.
ANN ARBOR, MICH.

There has been but little added to the literature of true heart thrombi since the very complete monographs of Robinson and Welch. Desultory reports of such conditions are not uncommon, but, as Welch has pointed out, many of the observations on so-called heart thrombi are really records of postmortem heart clots entangled in, but not organically attached to, the muscle columns and trabeculæ. True heart thrombi, whether of the pedunculated or ball variety, are of such uncommon occurrence that their occasional incidence would seem to warrant study of the clinical and pathologic sides of cases in which they have been found postmortem. And this seems especially important in so far as the possibility of antemortem diagnosis carries with it a not altogether worthless bearing on the prognosis in a given case. It does not appear necessary here to point out the practical value of antemortem diagnosis of this condition with regard to the application of therapeutic measures.

The term "cardiac thrombus" must be reserved for a solid or partly solid structure, primarily formed from blood elements, which develops in one or more chambers of the heart during life. Such a mass may be attached to the cardiac wall by a more or less altered base, or may exist as a free foreign body within a heart cavity. When cardiac thrombi are measured by this standard they are uncommon postmortem findings. This applies especially to those of the free, or "ball" variety.

Of the pedunculated variety of cardiac thrombus, Welch was able to discover thirty-three cases in 1899, while a much smaller number of "ball thrombi" are on record. Flat, broad-based, mycotic thrombi are more common. They may be the beginning of either of the two varieties mentioned.

The mode of formation of heart thrombi has been long a subject of difference. The early false conception of what was really meant by true thrombi was doubtless responsible for much confusion. The closer study of recent cases, from histologic standpoints, coupled with added knowledge of the chemical interaction of certain constituents of the blood, has elucidated some of the problems which vexed the early investigators. It is now commonly accepted that while in the production of a thrombus the individual exciting causes may vary widely, there are certain basic principles to which thrombus formation within the heart conforms. The first of these principles is that some damage done to the endocardium is concerned. This may be the result of bacterial, toxic or purely mechanical agents. Whatever the individual cause, the liberation of so-called thrombokinase, acting on the thrombogen in the circulating blood, with the formation of more or less fibrin, results in blood-clotting. This clot may be minutely local or early involve gross areas. The second factor in production of thrombi appears to be that of an increase of the hemagglutinins in the blood stream. This may be brought about by bacteria, either locally involving the endocardium or freely circulating in the blood stream. It would also seem that the introduction of certain proteid poisons into the circulation might be responsible for increased agglutination of red cells, with thrombus formation. In the light of recent researches, it does not seem that the increase of blood platelets in itself has any definite bearing on either agglutination or blood coagulation. It is not impossible, however, that development of necrotic foci locally in the endocardium as a result of microbic invasion might release into the blood stream hemolytic toxins, the result of which would be an increase of the thrombokinase in the heart cavities with coincident blood clotting by acting on blood elements. The third factor in the production of thrombi is that of slowing of the blood stream. Changes in direction of the stream with the formation of eddies may also have some bearing on the formation of thrombi in certain definite localities, as, for example, in the auricular appendages or between the muscle columns of the ventricles.

---

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixtieth Annual Session, at Atlantic City, June, 1909.

It might be of value to consider briefly the bearing of certain intracardiac and systemic conditions on the production and development of heart thrombi. The condition appears to be relatively infrequent in the majority of infectious diseases. It would seem, from tabulated statistics from various autopsy records in this and other countries, that, with the exception of influenza, tuberculosis, and perhaps rheumatism, cardiac thrombi are extremely uncommon findings in infectious disease. There is reason to doubt, however, the statement that cardiac thrombi are a rarity in syphilis, as I shall attempt to show later. Certain blood states are occasionally complicated by cardiac thrombosis, as, for example, chlorosis, leukemia and pernicious anemia. In the cachexias resulting from cancer (chronic), malaria, and the like, thrombi sometimes occur. Valvular lesions of the heart itself are usually secondary to infective processes in the endocardium. There is not uncommonly development of thrombi from such with vegetations as primary origin. Their organization and extension or contraction may be responsible for the valvular inefficiency or for insufficiency of the myocardium itself. Some writers have attempted from the meager statistics at hand to show the definite relationship of the development of heart thrombi to certain valvular disturbances. The much-quoted tables of Pawlowski would seem to demonstrate thrombosis of the left auricle was about five times as common as that of the right, and about ten times as common as in the left ventricle. Primary thrombosis of the right ventricle appears to be unknown. The usual cardiac finding, apart from general muscular insufficiency, particularly localized in one chamber wall, appears to be mitral stenosis. This applies particularly to cases of "ball thrombi." It is to be readily appreciated how obstruction at the mitral orifice mechanically alters the left auricular circulation, that chamber being especially suited to early sluggishness of its blood content. It is not infrequent, however, to find heart thrombi in the left auricle where there is no disablement of the mitral orifice—indeed, no apparent primary cardiac lesion whatever.

The thrombi are variously located. The majority spring from the septum, the foramen ovale, and the auricular appendage. It is possible, however, to have their bases at any part of the endocardium. The valve flaps do not escape. Thrombi formed with infectious vegetations as their bases may thus seriously interfere with the function of the valve flaps and aggravate, mechanically, a lesion otherwise of but moderate degree.

The condition of the arterial tree in general doubtless influences the formation of thrombi in the heart. This is especially true where a high grade of sclerosis exists generally, with the presence of atheromatous patches on the endocardium. It is to be expected, then, that the majority of cardiac thrombi are found in patients past the middle of life. This rule is not, however, absolute. Pawlowski's table shows two cases of pedunculated thrombi in patients below the age of 20, and Keating mentions the occurrence of thrombi in children afflicted with various infectious diseases.

The symptomatology of cardiac thrombosis varies with the location of the foreign growth within the heart. It is commonly admitted that, while the condition may be suspected during life, it can not be accurately diagnosed. Several authorities, notably Laennec, have held, however, that when in the course of a cardiac lesion the signs become anomalous and confused, with practical loss of the clinical picture of either definite cardiac lesion or typical cardiac inadequacy, one should suspect the possibility of thrombus formation. The signs and symptoms are those of impeded circulation. These seem to be most marked when the thrombus is located in the auricles. The thrombi located here are apt to be larger and to extend through the cardiac orifices into neighboring chambers. The inability of the more or less weak auricle wall to resist back-flow of blood and dilatation soon brings about pronounced alterations in the general circulation.

The three cases furnishing the basis of this communication occurred during the past two years at the University Hospital (Professor Dock's service). The cases were all of such interest that one might be pardoned submitting a rather full report of them. Of the three cases, the lesion was correctly diagnosed antemortem in one. Two patients were males, one female. Two were negroes. The ages were, respectively, 43, 56 and 60 years. The three cases exhibited, clinically, cardiac valvular lesions, the mitral flaps appearing to be the seat of the primary process. The reasons given for entering the hospital were shortness of breath, pain about the heart and the region of the stomach, general weakness, cough, with sputum, cyanosis, edema, and palpitation.

REPORTS OF CASES

CASE 1.—*Patient.*—L. J., negro, aged 43, gardener, entered the hospital, Out-Patient Medical Clinic, May 23, 1907, on account of extreme shortness of breath, precordial pain and distress and weakness.

History.—As is frequently the case in these patients, little could be obtained. The patient had had gonorrhea several times and there was a strong suspicion of lues. He had been well up to within two months of coming to the clinic. He then began to note weakness on exertion, shortness of breath and cough. There was abdominal discomfort in the left lower quadrant of the abdomen, although his bowels were regular. His appetite became poor and there was a tendency to belching of gas.

Examinations.—The dispensary examination revealed a rather well-built man with cyanosis of moderate grade at the ears, lips and finger tips. The heart was slightly enlarged in all directions. At the apex, the first sound was impure, and the second roughened. Both tricuspid sounds were impure, but not so harsh as the mitral sounds; the second pulmonic was very sharp and rough; there was a soft systolic bruit over the aortic area; the heart rhythm was very irregular; there was moderate sclerosis of the radials· the pulse was somewhat small, irregular and weak. The blood pressure, registered by the Stanton (12 cm. cuff) systolic 165 mm. Hg., diastolic, 118 mm. Hg. The lungs were negative.

The patient was placed on a mild diuretic and given saline cathartics. He left and was lost sight of for about a month, when he again came for examination. The shortness of breath, especially on exertion, was pronounced; there was great weakness and cough. The heart examination revealed no greater enlargement than when the patient was first seen. The sounds at the apex were now clear and distinct, and no murmurs were heard, although there was roughening of the mitral second, and both sounds were astonishingly sharp. There was noticeable accentuation of the second pulmonic sound, and a faintly heard systolic bruit was made out at the aortic area. The heart exhibited marked arrhythmia; there was no peripheral edema, nor enlargement of the liver or spleen. The pulse was small and very irregular. Strychnin and Carlsbad salts were ordered and rest insisted on. The patient then disappeared for about ten days.

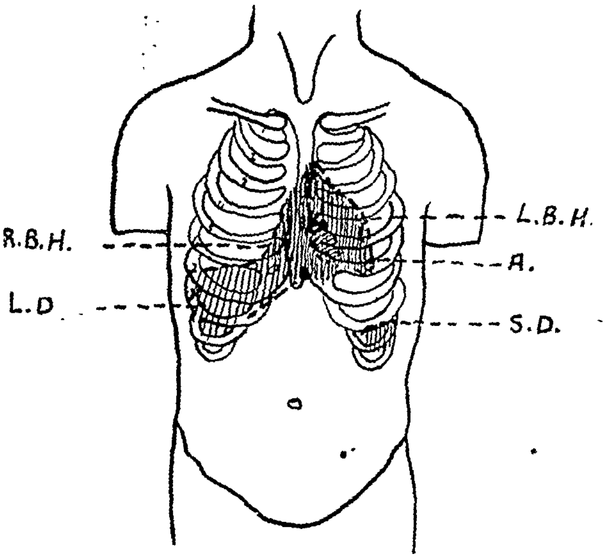

Fig. 1.—Case 1: Outlines of percussion dulness when patient entered hospital. L B H, left border of heart; A, apex beat; S D, splenic dulness; L D, liver dulness; R B H, right border of heart.

At his third appearance it was evident that he was in great distress. The cyanosis, cough, dyspnea, abdominal pain and weakness were extreme. He was ordered into the medical ward. At entry there were no murmurs heard over the precordia. The aortic sounds were very weak; the heart was somewhat enlarged in both directions (Dr. Van Zwaluwenburg); the systolic blood pressure registered with the Stanton (12 cm. cuff) 115 mm. Hg.

The patient was put to bed and his condition remained unchanged for twenty-four hours. At that time I was called to see him on account of his complaining of great pain in breathing, across the mid-epigastrium and the lower left axilla. He lay in the passive dorsal position, with eyes partly closed; his expression was anxious in the extreme; lips and ears were slightly cyanosed, but presented rather a striking degree of pallor; large drops of sweat stood on his forehead; the extremities were moist, without edema; the pupils were equally dilated, but sluggish.

Heart: Apex in fifth space, just outside the mid-clavicular line. The right border extended slightly beyond the right edge of the sternum at the fourth right interspace; the right border could not be made out higher up. The upper boundary on the left was at the upper edge of the fourth rib, in the left parasternal line; the left edge was made out about 1 cm. outside the mid-clavicular line in the fifth left space. (Fig. 1.) On auscultation the sounds were very weak at the apex; the first was murmurish. The second pulmonic was accentuated and divided. It was very difficult to make out the sounds over the base; the aortic sounds were very weak. There was moderate arrhythmia, with occasional extrasystole. The radial pulse was very small, irregular, but coincident with the heart beat. The vessels of the neck, especially on the right, were moderately engorged, but positive pulsations were not noted in the jugulars. The blood pressure was 116 (Stanton, 12 cm. cuff). Liver and spleen not enlarged.

Lungs: Pleuritic friction in the left axilla and back, with diminished resonance in both lower backs, more on the left.

Abdomen: Tense and difficult to examine, especially full in the mid-epigastrium; deep palpation impossible on account of muscle spasm throughout; there was pain on moderate pressure in the epigastrium and in the left lower quadrant. Catheterization revealed stricture in deep urethra.

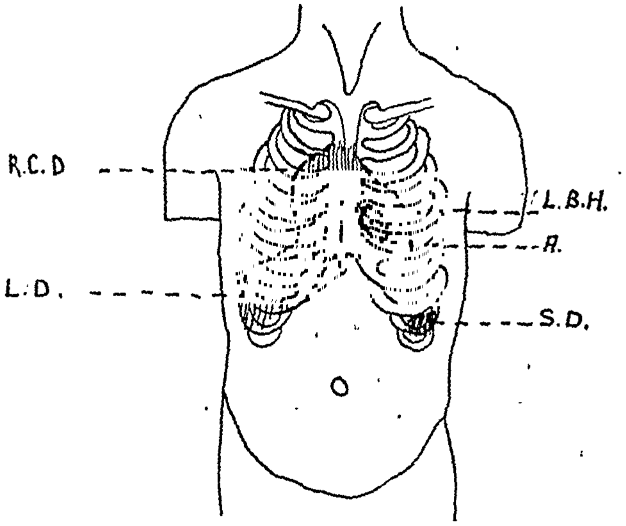

Fig. 2.—Case 1: Outlines of percussion dulness two days before death. (Postmortem: Thrombosis of right and left auricles.) L B H, left heart border; A, apex; S D, splenic dulness; L D, liver dulness; R C D, right cardiac outline to right of sternum.

The man was given morphin, enemata, and cathartics; ice was placed locally over precordia and left thorax. The following day his temperature rose to 101 F. in the morning and restlessness was extreme. It was impossible to keep the man in bed, the greatest relief being when he was walking about. His expression was frightened; his face and neck a dusky pallor and covered with huge drops of cold sweat; breathing audible and of the Cheyne-Stokes type. Bowels had not moved in spite of cathartics and enemata. Dyspnea and abdominal pain were marked. The breathing was distinctly audible throughout the ward.

The heart showed distinct changes from the day previous. (Fig. 1.) The apex beat could neither be seen nor felt. By auscultation it was made out in the fifth left space, just within the left mid-clavicular line. The heart had, however, greatly enlarged towards the right, and the enlargement was of peculiar outline, when associated with other clinical findings. In the fifth right space the right cardiac border could be made out nearly three fingers' breadths to the right of the sternum. The line of dulness extended upwards at about the same distance from the right edge of the sternum almost to the second rib, where it curved rather sharply inward to meet the sternum at the angle of Ludwig. There was slight outward bulging in the second and third spaces. This atypical rightsided enlargement of cardiac dulness was not associated with noticeable venous engorgement of neck vessels and there was no positive venous pulsation in the jugulars. Liver and spleen were negative; there was no peripheral edema. (Fig. 2.) On auscultation, the sounds at the apex were weak. A soft, blowing, systolic bruit could, however, be made out at the mitral area, the systolic bruit being well heard in the axilla and the left back. Over the tricuspid area the murmur with the first sound became louder and more prolonged. It was carried well up the left edge of the sternum. At the third left costosternal junction there was a suggestion of soft, blowing, diastolic bruit. The sounds over the base were audible with difficulty. The second pulmonic was divided, and a late diastolic bruit was made out. In the aortic area the sounds were only occasionally audible. There was marked arrhythmia—a veritable "delirium cordis." The radial pulse was barely palpable, rather quick and did not appear to differ in rate with that of the heart. The lung examination revealed pleurisy on the left with airless tissue in the back. The abdomen was still rigid and tender. The bowels could not be made to respond to purgatives or enemata.

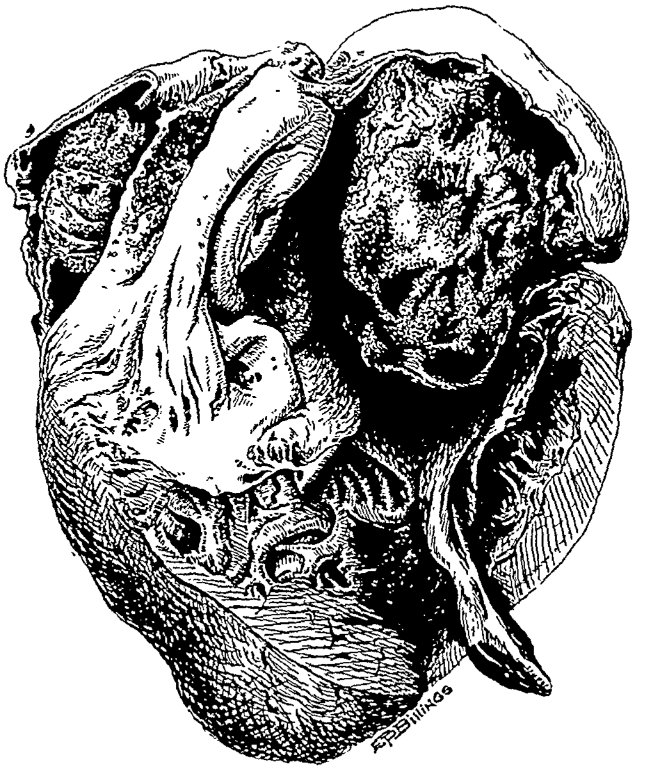

Fig. 3.—Case 1: Heart showing thrombus in right auricle extending through the tricuspid orifice into the right ventricle. (From the Pathological Museum of the University of Michigan, Specimen No. H. 46. Courtesy of Dr. Aldred Scott Warthin, Director.)

The condition described continued about the same for another day and then the patient suddenly expired while being bathed.

Postmortem Examination (Prof. A. S. Warthin, prosector).—Seven hours after death.

Clinical Diagnosis: Mitral, tricuspid and aortic regurgitation; suspected thrombosis of right auricle; pleurisy, pneumonia (terminal); nephritis; cystitis; intestinal obstruction; infarction.

Pathologic Findings: Heart: Subepicardial fat increased; small subepicardial hemorrhage on anterior surface; few on posterior surface; ventricles contracted; both auricles filled with currant-jelly clot. Right heart: Auricle enormously dilated; extended about four fingers' breadths beyond right sternal margin; muscle fibers separated. Ventricle wall measured 4 to 6 mm. On opening the right ventricle, there was seen a clot extending through the tricuspid orifice, in parts firmer than in others. The base of this clot was adherent to the wall of the right auricle, filling the ear. It was dark yellow, tough and fibrous. On cutting into this base there were cyst spaces filled with broken-down and altered blood. These older clots were gradually merged into more recent clots extending continuously through the tricuspid ring. (Fig. 3.) Left heart: In the left auricle was a large currant-jelly clot attached to a firmer organized clot in two places. The main attachment was in the ear of the auricle, and the smaller over the posterior wall. There was a rather recent thrombus at the mitral ring. Just between the mitral flaps was a firm white clot, entangled between the chordæ tendineæ and attached to the clot in the auricle. This was continuous to a clot extending to the aortic ring. At the base of the clot on the mitral valve was an area of sclerotic endocardium. The chordæ tendineæ were not retracted or thickened. The ventricular wall was light brownish-red, slightly cloudy and firm; there was slight fatty degeneration. (Fig. 3.)

Lungs: Recent hemorrhagic infarcts; (embolic) passive congestion and edema.

Pulmonary vessels: Organizing thrombi.

Liver: Extreme passive congestion; nutmeg liver and icterus.

Kidneys: Cloudy swelling; small healed anemic infarcts; recent sclerosis of renal vessels.

Adrenals: Chronic passive congestion; excessive fatty degeneration.

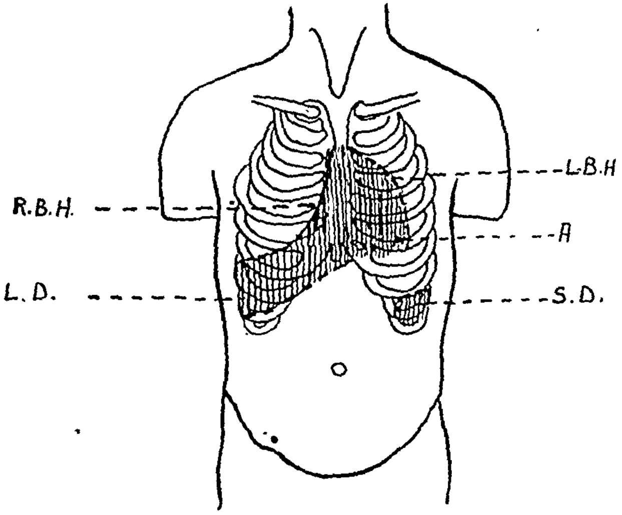

Fig. 4.—Case 2: Outlines of percussion dulness. (Postmortem: Thrombosis of left ventricle.) L H B, left heart border; A, apex beat; S D, splenic dulness; L D, liver dulness; R H B, right heart border.

Pancreas: Atrophy; sclerosis of vessels; some fatty infiltration.

Prostate: Chronic prostatitis.

Spleen: Chronic passive congestion; anemic infarction.

Pathologic Diagnosis.—Summary: Cardiac thrombosis; chronic interstitial myocarditis; obliterative endocarditis, probably syphilitic; arteriosclerosis; thrombosis of pulmonary vessels; hemorrhagic infarcts of lungs; anemic infarcts of spleen and kidneys; chronic passive congestion of all organs.

Case 2.—*Patient.*—J. B., male, aged 56, merchant, American, was brought to the hospital by his brother on account of "heart disease," "Bright's disease" and addiction to morphin and possibly other drugs.

History.—Family history negative so far as could be determined. Patient had scarlet fever as a child; diphtheria at 15 (ill six weeks; delirious); malaria in southern Missouri, at 26, and attacks continued for some time after coming to Michigan; paroxysms every other day at first, then daily; "remittent fever" at 44; denied gonorrhea and lues. Took Keeley cure at Dwight two years previous to entering the hospital and had not taken intoxicants since. Previous to that time had been a hard drinker and had taken Keeley cure twice with relapses. He had a cough for fifteen years and at times it was very severe, the patient having raised much sputum, and he said some of it was deeply blood-stained; of late had had "inflammation of the bladder" and incontinence of urine.

Examination.—A large, heavy man of asthmatic type. Skin of face sallow and dusky; slight cyanosis of lips, chin, ears, finger tips; slight edema of feet and legs; coughed frequently and raised mucopurulent sputum.

Thorax: Large, deep, short, broad. Heart: Diffuse pulsation in the region of the left nipple; apex beat not distinctly seen or felt. Dulness, on the fourth rib, outward to the midclavicular line, and inward to just beyond the right edge of the sternum, a total width of 14.5 cm. (Fig. 4.) Auscultation: Sounds very weak at apex; pulmonary second very weak; aortic second weak, with soft diastolic murmur (auscultation difficult on account of the harsh breathing; radials very small; and pulsations irregular. Lungs: Harsh breathing throughout, with occasional crackling râle; diminished resonance in the right back.

Liver dulness small.

Abdomen: Somewhat distended; dull in the dependent parts.

Blood pressure: Systolic, 152 mm. Hg.; diastolic, 108 mm. Hg. (Erlanger, 15 cm. cuff).

Urine: Small amounts of albumin with few granular and hyaline casts; pus with numerous cocci; few red blood cells.

Blood: Reds, 5,280,000; whites, 8,600; Hg. 95 per cent. Tallquist.

Sputum: Thick, tenacious, mucopurulent, copious; many large cocci in pairs; many small cocci in groups; many polynuclear leucocytes; many "heart failure cells" and some red blood cells.

The patient remained under observation for about three months. At times there were periods of considerable comfort, with frequent relapses. He finally developed extreme myocardial inefficiency, which, coupled with infarction and edema of the lung, caused his death.

Postmortem Examination (Prof. A. S. Warthin, prosector).—Twelve hours after death.

Clinical Diagnosis: Dilatation of heart; stenosis and insufficiency of mitral valve; infarct of lung; hypostatic congestion; chronic bronchitis; chronic nephritis; nutmeg liver; terminal pneumonia?

Heart: Enlarged in all directions; dilated and hypertrophied; marked dilatation and hypertrophy of left ventricle; fibrous myocarditis and hemorrhagic infarction; sclerosis of coronaries, anemic infarction of ventricular wall, near the apex of the left ventricle. In the left ventricle was a moderately large thrombus, with organizing base, attached to the ventricle wall. The ventricle was greatly dilated, and there was relative insufficiency of the mitral valves. The endocardium showed atheromatous patches; the aorta was dilated and atheromatous: the aortic flaps were thickened and stiffened. (Fig. 5.)

Lungs: Chronic passive congestion; edema; old and fresh hemorrhagic infarcts; multiple emboli.

Spleen: Chronic passive congestion; atrophy; sclerosis.

Kidneys: Anemic infarct in stage of organization; chronic passive congestion; chronic parenchymatous nephritis; multiple embolic infarcts.

Adrenal: Congestion, with marked fatty change.

Liver: Nutmeg liver; early stage of cirrhosis (in part a central cirrhosis and in part of the atrophic type), small, miliary tubercles.

Testis: Edema; chronic congestion; small cysts in epididymis; calcified thrombus.

Pancreas: Fatty atrophy; increase of interstitial connective tissue; unusually large hyperemic islands of Langerhans.

Stomach: Chronic catarrhal gastritis.

Vessels: Sclerosis; atheroma.

Pathologic Diagnosis.—Summary: Cardiac thrombosis and infarction; cardiac hypertrophy; relative mitral insufficiency; chronic congestion of all organs; hemorrhagic infarction of lungs; anemic infarction of kidney; early stage of hepatic cirrhosis; atrophy of pancreas; arteriosclerosis and atheroma (syphilis?).

Case 3.—*Patient.*—M. C., female, aged 60; negress, housewife, was sent to the hospital by her physician on account of shortness of breath, cardiac distress; chronic cough; swelling of feet and ankles and insomnia.

History.—Patient denies lues and gonorrhea; had not been ill much in life; always worked hard. About ten years ago she said she fell and broke leg; said she had had shortness of breath on exertion ever since; had had "weakness" in region of heart which prevented her moving about much or doing heavy work; about six months ago had a severe fright from house getting on fire. She became very short of breath afterward; felt very weak and could not lie down at night; ankles and legs began to swell; and recently thought that abdomen had become larger.

Examination.—Patient, a rather emaciated negress, propped up in bed, expression anxious; frequent cough; mucous rattle in throat; marked dyspnea; eyes injected; moderate cyanosis of lips, ears and extremities; tense edema to knees, with scaly eczema over legs; neck vessels injected and tortuous.

Thorax: Short, deep and broad; interspaces retracted during inspiration; thorax moved *en cuirasse;* right side below nipple much fuller than left; no Litten's shadow seen on either side; lung-liver border at seventh rib, mid-clavicular line. Percussion: Lungs, hyperresonance over both uppers with fair resonance in both axillæ. Auscultation: Large and small, moist and dry râles throughout, more especially on the left side. No alterations in voice transmission.

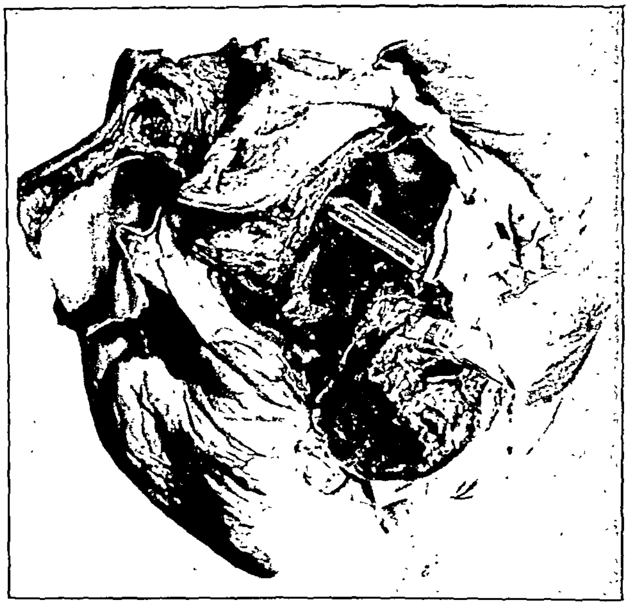

Fig. 5.—Case 2: Heart showing thrombus in left ventricle. (From the Pathological Museum of the University of Michigan. Specimen No. H. 65. Courtesy of Dr. Aldred Scott Warthin, Director.)

Heart: Apex beat in the fifth left space, 8.5 cm. from the median line; dulness extended two fingers' breadths to right of sternum in the fifth right space; one finger's breadth to right in fourth right space. The upper boundary of the cardiac dulness was at the upper edge of the fourth rib in the left parasternal line; the left edge was 11.5 cm. from the mid-line in the fourth left space. (Fig. 6.) There was noticeable pulsation in the middle line at the base of the xyphoid. Auscultation: First sound at apex was impure and occasionally divided; both features were more noticeable as one went toward the base of the xyphoid. The sounds over the base were very weak with the exception of the pulmonic second sound, which was moderately accentuated and murmurish. The radial pulse was small, quick, slightly irregular and compressible, with difficulty. The blood pressure was systolic, 242 mm. Hg.; diastolic, 168 mm. Hg. (Erlanger apparatus, 15 cm. cuff).

Abdomen: Rose three fingers' breadths above the level of the ribs; was rounded and circumference measured 92 cm. just below the navel. No pain points; no muscle spasm; no dulness in flanks. Liver, spleen and kidneys not felt. Glands negative throughout.

Urine: Slight traces of albumin, with small amounts of pus and blood.

Blood: Reds, 4,824,000; whites, 12,150; Hg. 95 per cent. (Tallq.).

Sputum: Yellow, ropy, thick and tenacious. Many polynuclear leucocytes and few heart-failure cells.

The patient was kept under observation about one month. She showed some improvement at the first part of her stay. Under appropriate medication, blood pressure became lower; orthopnea became less marked; the cardiac dulness diminished somewhat in size and the cough became less. About a week before her death she showed signs of failing cardiac action. Cheyne-Stokes breathing developed, edema of the lungs supervened and the patient died quietly. Towards the end of her illness she developed facial erysipelas. The heart again dilated, and a loud systolic bruit was audible at the apex. The sounds over the base continued weak. The neck veins became greatly engorged, particularly the left, external jugular, which pulsated noticeably.

Postmortem Examination (Prof. Aldred S. Warthin, prosector).—Performed eleven hours after death.

Clinical Diagnosis: Double mitral; cardiac dilatation and hypertrophy; tricuspid regurgitation; emphysema; pleural effusion (?), chronic congestion of kidneys; chronic interstitial nephritis; erysipelas facialis.

Heart: Pericardium adherent to border of left lung; tension greatly increased; 50 c.c. of turbid fluid in pericardial sac. The heart was enormously enlarged; there was great arching of the septum to the left; the heart lay nearly transversely. The right auricle was greatly distended and formed about one-third of the entire heart size. The position of the heart was such as to rotate the pulmonary artery to an angle of 45 degrees. Between the pulmonary artery and the aorta was a thick, tendinous spot. The heart muscle was hypertrophic, with numerous atrophic fibers, however. It showed brown atrophy. The mitral valve showed an old sclerotic endocarditis. There was stenosis of the mitral flaps, of the true "buttonhole" type. In the left auricle was a moderately large organizing thrombus, attached by a broad base, at which point the endocardium was greatly thickened. (Fig. 7.) The right heart was markedly dilated, particularly the right auricle; the tricuspids were relatively insufficient. The aorta showed atheroma, marked sclerosis and calcification.

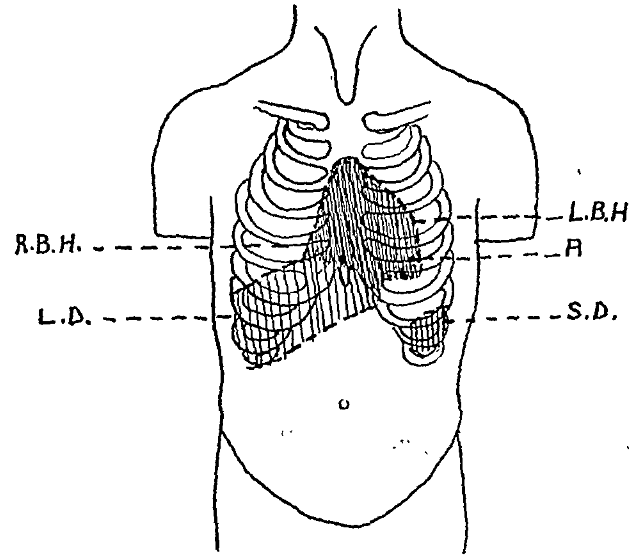

Fig. 6.—Case 3: Outlines of percussion dulness. Postmortem: "Buttonhole" mitral with thrombosis of left auricle.) L H B. left heart border; A, apex beat; S D, splenic dulness; L D, liver dulness; R B H, right heart dulness.

Liver: Extreme nutmeg liver; secondary cirrhosis.

Spleen: Atrophy and chronic passive congestion.

Lungs: Brown induration; edema; recent hemorrhagic infarcts; old calcified tubercle.

Kidney: Acute and chronic passive congestion; some atrophy and cloudy swelling; bacterial emboli in many of the small arterioles.

Adrenals: Passive congestion; atrophy.

Stomach and Intestine: Chronic passive congestion; stasis; gastritis and enteritis.

Uterine Wall: Fibroma.

Pathologic Diagnosis.—Summary: Erysipelas facialis; mitral stenosis; relative tricuspid regurgitation; thrombosis of auricle; dilatation of right heart; brown induration of lung; chronic passive congestion and atrophy of all organs; sclerosis and atheroma of aorta; healed tubercle in lung; slight goiter.

SUMMARY

Diagnosis.—The three cases here detailed present many features in common, while in certain respects they differ. The patients were past middle life. In all there was a fair possibility of syphilis. In each case the patient exhibited phenomena of cardiac insufficiency, in the main valvular. In all the cases, the mitral valves were affected. In but one was there stenosis. In this case, the stenosis was poorly manifested, clinically, with the exception of the early enlargement of the right side of the heart. In all the cases, postmortem examination showed the presence of emboli in various organs.

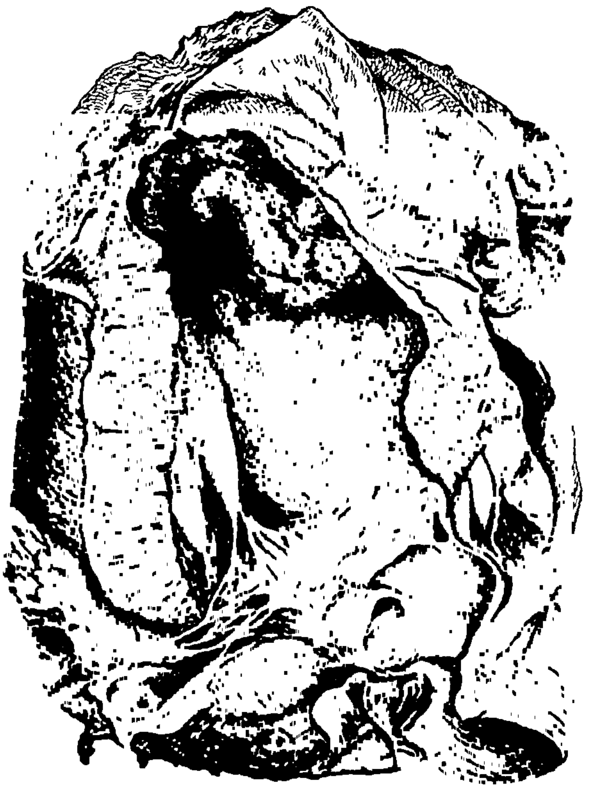

Fig. 7.—Case 3: Heart showing "buttonhole" mitral orifice with thrombus in left auricle. (From the Pathological Museum of the University of Michigan. Specimen No. H. 71. Courtesy of Dr. Aldred Scott Warthin, Director.)

With respect to the thrombi themselves, a wide distribution is noted. In Case 1, the right heart, especially the auricle, was the primary seat of the thrombus. As circulation became interfered with, the mass extended into the right ventricle. There was, however, thrombus formation also in the left auricle, with a chicken-fat clot entangled in the chordæ tendineæ and interfering, at the end, with the free working of the aortic flaps. In Case 2, the ventricular wall gave rise to the thrombus. In this case, the signs of cardiac disease pointed strongly to the aortic valve being at fault, but postmortem the valve showed little change. In Case 3 is seen the rather typical, text-book heart thrombus, with mitral stenosis, impeded circulation in the left auricle, with pulmonary congestion and dyspnea early developing, together with early enlargement of the right heart. The termination occurred with the dilatation of the right auricle after the tricuspid "safety valve" had thrown too great a strain on the weakened auricle.

Before closing I wish to call attention to certain aspects of Case 1 which rendered antemortem diagnosis of auricular thrombosis fairly possible. It will have been noted that the case first appeared with a somewhat atypical cardiac condition, namely, slight enlargement of the heart, but associated with extreme dyspnea, precordial distress and cyanosis, together with more or less pallor. Various murmurs and alterations in the character of the valve sounds were discovered, but neither murmurs themselves nor their location or propagation were definite enough to warrant the diagnosis of any particular valve lesion. After the patient entered the hospital, it was observed that prostration, precordial distress, restlessness and dyspnea, developed out of all proportion to the clinical findings in the heart itself. At the same time sudden, severe pains in the pleura, lungs and abdomen were noted—these strongly suggestive of infarction from emboli. As the case approached its termination, all the signs of failing cardiac action appeared from the point of view of the heart examination itself, but outside the heart the clinical condition was most atypical. The heart examination pointed strongly to mitral and tricuspid leakage, but extracardiac evidences were strangely lacking. Cyanosis was rarely marked; peripheral edema was extremely slight—indeed, absent till just before death; congestion of the liver, with liver pulse, was clinically absent. The spleen was not engorged. I would also call attention to the condition of the neck veins. At no time did they exhibit more than moderate engorgement, even when the signs of tricuspid insufficiency had been established for at least two days. There was absolutely no positive venous pulsation in either jugular vein, nor were positive venous pulsations noted in other veins, nor in the liver. I offer as explanation of this phenomenon the suggestion that the regurgitation wave from the right ventricle was changed in direction, or, indeed, broken up entirely, by its impinging on the large and constantly increasing heart-clot in the right auricle. So long as the auricle itself was able to propel a moderate amount of blood into the right ventricle, the circulation was maintained. It was only when the thrombus intruded on the right ventricle through the tricuspid orifice that stagnation became so great in the auricle as to bring on sudden cardiac dilatation and death. It does not appear to me that dilatation of the auricle along with sluggish blood stream could absorb, as it were, systolic pulsation from the right ventricle after the tricuspids had given way. This condition would be manifested by far greater venous congestion—in the neck veins and peripherally in the liver and extremities—than Case 1 showed. This is admirably demonstrated in Case 3, in which there was a buttonhole mitral with thrombus in the left auricle. Here the early dilatation of the right heart was promptly shown by peripheral edema, enlarged liver, and congested, pulsating veins in the neck, in addition to early enlargement of the right heart. It would seem to me, therefore, that the antemortem diagnosis of certain heart thrombi is not altogether impossible if the physical signs are carefully observed and recorded. And of these physical signs I would lay especial stress on atypical peripheral vascular manifestations with the more or less characteristic auscultation and percussion signs in the heart itself. The manifestations of embolic process should always furnish significant information.

With respect to the treatment of cardiac thrombi when the diagnosis appears likely, there can be little said. The question of how soon the case will terminate fatally is the leading one. The suspicion of a thrombus being present in the heart completely changes the picture from the prognostic standpoint, and certainly limits one's hopefulness with regard to whipping into line by drugs a heart whose compensation only appears to be failing.

In the preparation of this paper, I have been greatly helped by the kindness of Prof. A. S. Warthin, of the Department of Pathology of the University of Michigan, and I herewith express my appreciation.

305 South State Street.

A NEW AND SATISFACTORY APPARATUS FOR ETHERIZATION IN OPERATIONS ABOUT THE FACE AND UPPER AIR PASSAGES *

ALBERT H. MILLER, M.D.
Visiting Anesthetist to the Rhode Island and St. Joseph's Hospitals
PROVIDENCE, R. I.

The problem of satisfactory anesthesia for operations about the face and upper air passages is worthy of study. The nature of the operations is such that no inhaler or cone can be kept constantly over the face and nose of the patient. It may be necessary to keep the mouth open throughout the operation. Under these conditions it has been impossible by the usual methods to produce a smooth anesthesia.

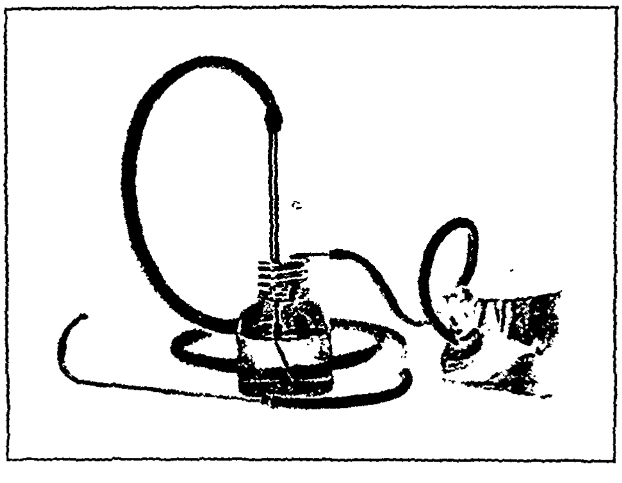

Fig. 1.—The foot pump, vaporizer and mouth tube connected.

The patients have been anesthetized in the following ways:

1. By nitrous oxid or ethyl chlorid: The anesthesia produced by these agents is too short for the majority of the operations.

2. By charging up the patient with ether and allowing him to recover partially as the operation goes on, then repeating this process as many times as necessary: This method is dangerous and seriously impedes the operation.

3. Chloroform administered with the Junker apparatus—the routine method in England: Chloroform is a dangerous anesthetic for all these operations, and especially in the adenoid cases, in which the patients are

---

* Read in the Section on Laryngology and Otology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

often of the lymphatic diathesis and liable to sudden death from syncope. Moreover, with the Junker apparatus there is the possibility of pumping liquid chloroform or ether into the air passages of the patient. Crile's apparatus is open to a similar criticism. The apparatus of Brophy does away with this serious objection.

4. Some forms of apparatus depend on the changing temperature of a hot-water bath to vaporize the ether. The amount of ether vapor is accordingly inexact and changeable. The forms of apparatus which depend on air bubbling through ether at the room temperature do not vaporize enough ether to maintain satisfactory anesthesia.

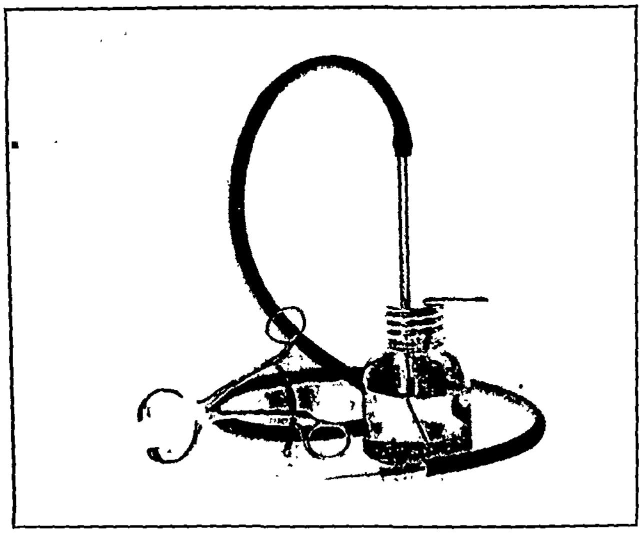

Fig. 2.—The vaporizer and the mouth gag connected.

THE APPARATUS

The apparatus here described for the first time is simple and safe. It provides for the continuous etherization of the patient and interferes in no way with the operation. It was first used on Jan. 12, 1906, and in the past three years has been employed in over 1,000 cases, including operations on the lip, tongue, mastoid, nasal septum, frontal sinuses and Gasserian ganglion, in operations for goiter, for removal of the superior maxillary bone, and for many adenoid and tonsil operations.

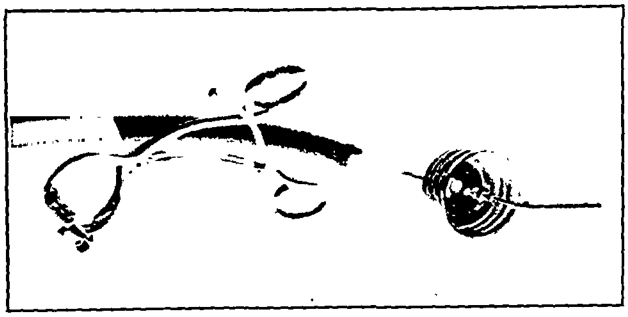

Fig. 3.—The cap of the vaporizer, showing the small atomizer arranged to spray into the outlet tube. The mouth gag.

The apparatus consists of a vaporizer, a foot pump, a mouth gag, and other accessories, together with the rubber tubing necessary for connecting these to the vaporizer.

The vaporizer consists of a glass jar, with a capacity of 8 ounces, hermetically closed by a screw cap. In the cap are fixed an inlet tube, 1/8 inch in diameter and a vertical outlet tube, 1/4 inch in diameter. Inside the jar and connected with the inlet tube is a small atomizer arranged to draw ether from the jar and spray it inside the outlet tube, which is 5 inches long. When the ether spray reaches the top of this tube it has been converted into a vapor, imperceptible except by its odor. (Fig. 1.)

This apparatus will vaporize 15 ounces of ether in an hour. As the ether is sprayed into the outlet tube and not against the side of the jar as in the ordinary nebulizer, the vaporizer is very sensitive to changes in the air pressure supplied to it. The foot pump, which supplies the air pressure for the vaporizer, may be supplanted by a cylinder of oxygen or compressed air. A hand bulb does not provide enough pressure to work the vaporizer. It is impossible to force liquid ether into the outlet tube by pumping air into the inlet tube and *vice versa.*

A rubber tube 1½ feet long connects the foot pump with the vaporizer. The outlet tube is connected by 4 or 5 feet of rubber tubing to a mouth or nasal tube. (Fig. 2.) As the ether vapor passes through this rubber tube it becomes warmed to the temperature of the operating room. This tube is divided six inches from the mouth or nasal tube, the parts being joined by a glass connection so that the short end may readily be removed for sterilization.

The mouth gag, which is made from the design of Dr. Frank B. Sprague, is not readily dislodged, does not obstruct the breathing., and in no way interferes with the operation. The handles are so curved as to be readily grasped. In one jaw of this gag is incorporated an ether tube 1/8 inch in diameter. (Fig. 3.) When the gag is placed in the left side of the mouth, the tube is in the upper jaw of the gag and its opening is directed backward toward the fauces.

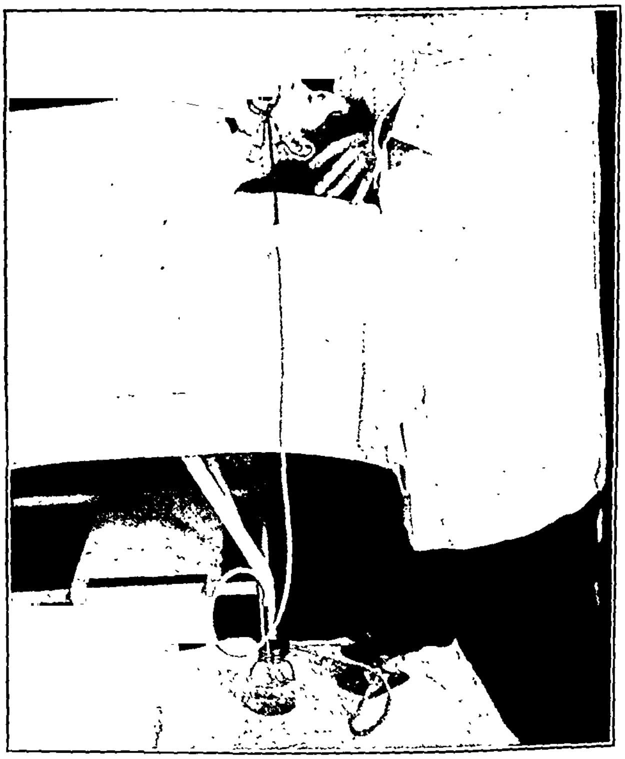

Fig. 4.—The apparatus in use for an adenoid operation.

The mouth tube is a metallic tube of 1/4 inch bore so curved that when it is hooked into the angle of the mouth, its opening is directed backwards towards the fauces. The nasal tube is a soft rubber tube 1/8 inch in diameter and 14 inches long. A mark, at a distance of 7 inches from the end, indicates the extent to which it should be introduced in an adult. From failure to notice this mark, the tube may be pushed so far into the esophagus that a gastric anesthesia results.

The Pynchon nasal tips may be used with this apparatus.

ADMINISTRATION OF ANESTHETIC

The vaporizer, filled two-thirds full of ether, is placed on the floor at the head of the operating table (Fig. 4). Care is taken to place the vaporizer where it will not be accidentally overturned. The foot pump is attached and the long tubing is brought up from the outlet tube of the vaporizer to the head of the table. The short tube attached to the gag, mouth or nasal tube is sterilized with the surgeon's instruments. Ether is, at first, administered in the usual way. When the operation is about to be commenced, the surgeon arranges to suit his convenience the gag, mouth or nasal tube. The anesthetizer connects the long tube to the short one and continues to administer ether by working the foot pump at a greater or less rate of speed.

It is necessary to notice constantly through what channel the patient is breathing. It is almost useless to pump ether vapor into the mouth of a patient who is breathing through the nose and *vice versa*. In a frontal sinus operation, when the anesthetic vapor has been considerably diluted by air coming through the open sinus, the closing of the sinus in the course of the operation is quickly followed by increased depth of anesthesia. During the early stages of the adenoid operation the patient is breathing entirely through the mouth, and no trouble is found in maintaining anesthesia by the tube in the mouth gag (Fig. 4). As the nasal passages are cleared, however, nasal breathing may so dilute ether vapor that the patient may begin to recover consciousness. It is then sufficient to cover the face with a towel while the vaporizer is worked for a few minutes and complete anesthesia is restored.

Considerable experience with this apparatus warrants the conclusion that, with careful attention, it solves the problem of satisfactory anesthesia for operations about the face and upper air passages.

[THE DISCUSSION ON THIS PAPER IS ON PAGE 1381.]

VAGINAL HYSTERECTOMY

A NEW OPERATIVE TECHNIC TO ESTABLISH A SOUND PELVIC FLOOR AND TO PREVENT CYSTOCELE *

RALPH ELMERGREEN, M.D.
MILWAUKEE, WIS.

I intend to present in this paper a new technic that will prevent cystocele following vaginal hysterectomy.

The etiology, symptomatology and diagnosis of the various pelvic lesions calling for some radical gynecic procedure will not be considered at this time.

GENERAL CONSIDERATIONS

The gynecologist of to-day recognizes and, with few exceptions, makes use of three methods of removal of the diseased pelvic organ.

(a) Abdominal hysterectomy.
(b) Vaginal hysterectomy.
(c) Vagino-abdominal hysterectomy.

Each of these methods has its specific indications, though, unfortunately, the method of choice is more frequently determined by the prejudices and experience of the operator than by the anatomic and pathologic indications of the patient. The vaginal route alone will be considered in this paper.

Vaginal hysterectomy is a difficult operation and should only be performed by the experienced pelvic operator. The disrepute into which the vaginal route had fallen at the close of the last century was not due to a higher mortality, for, as a matter of fact, the comparative mortality has always remained lower, but rather to the many accidents following in the wake of the surgeon accustomed, by years of training, to rely wholly on sight and very little on touch in his pelvic work.

When restricted to its legitimate field of application the advantages of removing the diseased or displaced uterus with or without the appendages, by the vaginal route, are very pertinent. The more experience we gather the more we, as surgeons, become convinced that, in order to arrive at the best results in operative work, marked concessions must be made to the prejudices of the laity.

The horror of the abdominal incision unquestionably has cost many lives.

The advantages of the vaginal route over that of the abdominal route are not alone psychic and esthetic. In septic cases in which drainage is necessary, and the Fowler or sitting postoperative position is assumed, the mortality of vaginal hysterectomy to-day is practically *nil*.

In carcinoma of the fundus of the uterus, with a movable uterus and without glandular metastasis, the vaginal operation should always be the procedure of choice. The non-occurrence of shock, the early convalescence and the apparent absence of mutilation in vaginal hysterectomy can not possibly be urged too strongly in favor of this method. In my cases the recovery after vaginal hysterectomy was not only uneventful, but in no instances was there any postoperative suffering from gas, shock or any of the many discomforts that commonly attend our abdominal work. I recall that one well known surgeon compares the recovery from vaginal hysterectomy with that of convalescence from a normal childbirth.

In elderly women in whom the abdomen is thick and pendulous, vaginal celiotomy is always the operation of choice, unless expressly contraindicated.

In women who have passed the climacteric, the prolapsed uterus should be removed in all cases *per vaginam*. To retain the uterus in these cases and fix it to the anterior vaginal wall as a cushion for the bladder serves neither a surgical nor an esthetic purpose. The uterus in women of this age is a useless organ, of no sexual significance, often diseased and hypertrophic or subject to irritation and hyperplasia, if not to carcinoma, and its retention in the pelvis by fixation serves absolutely no good end.

The various mechanical devices both for correcting the retroflexed or prolapsed uterus, including the old Alexander-Adams operation, and the later Gilliam method, and the still later Webster-Boldt or Baldy operation, whereby the round ligaments are made to serve as a cushion for the displaced uterus, all fail markedly in not overcoming the concomitant cystocele, urethrocele and general vaginal fulness for which these patients ask relief.

There was a day when we amputated the cervix for carcinoma of the cervix. That day has happily passed. Yet I sometimes fear now that some of us are perhaps leaning too far toward radicalism as a result of our early incomplete work. Led by Wertheim, many leading gynecologists of to-day doubt the advisability of even ever removing the cancerous uterus from below. They insist on abdominal section, with complete pelvic evisceration in all cases. Surgically their position is apparently invulnerable, yet when we consider the enormous immediate mortality, even in selected cases, and the technical difficulty involved in this two-hour parametrium dissection, no conscientious man can blame some of us for being less radical, and thereby reducing the immediate mortality, even if we have to be more guarded in the eventual prognosis.

---

* Read before The State Medical Society of Wisconsin, July 2, 1909, Sixty-Third Annual Meeting.

The wider the fame and the more expert the technic of the operator, the more daring he becomes in forcing his views on radical pelvic work. Not many months ago I witnessed three operations for cancer of the cervix with involvement of the lower glands, performed by one of the ablest continental surgeons. The operations were all of the radical nature as advocated by Wertheim. In every case a clean box was made of the pelvis, with an alarming liberation of the ureters and a complete dissection of the parametrium and the lower glands. The work, from the surgeon's viewpoint, was ideal in its completeness, yet the patients all promptly died. I am satisfied that in these cases the extirpation of the uterus and appendages *per vaginam* would have given more happy end-results.

The radicalism so persistently urged by Ries, Wertheim, Werder and Clark, early led Schuchardt to modify his vaginal technic by making his incision quite free of the cervix into the paravaginal and pararectal tissues, cutting through the left labium, the perineum, entering the ischiorectal fossa, and exposing the distal portions of the broad ligaments. With the same liberal disregard of tissue the vesicouterine pouch is now entered, and an incomplete dissection of the ureters and the parametrium is made possible. This operation, while less radical, is technically more difficult than the Wertheim dissection.

CONTRAINDICATIONS FOR VAGINAL HYSTERECTOMY

A congenitally small vagina, or a vagina that has undergone senile atrophy, with a fixed uterus, or a cervix held up and backward that can not be drawn down far enough to ligate the lateral vessels, would mechanically preclude selection of the vaginal route for celiotomy.

In advanced carcinoma of the uterus with parametrium extension and probable glandular metastasis, abdominal hysterectomy is the operation of choice.

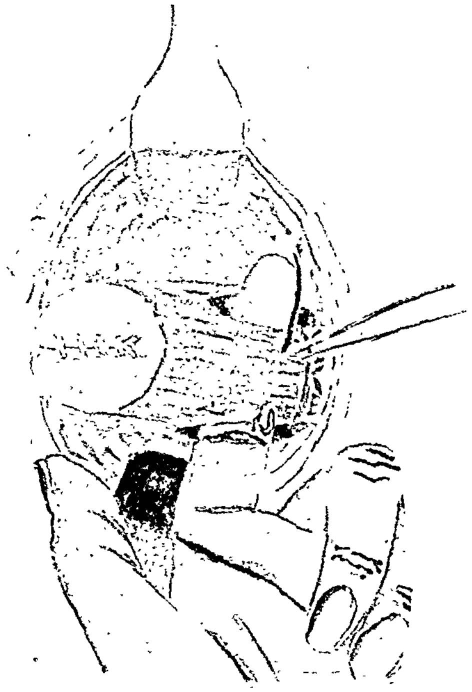

Fig. 1.—Method of hooking up the broad ligament.

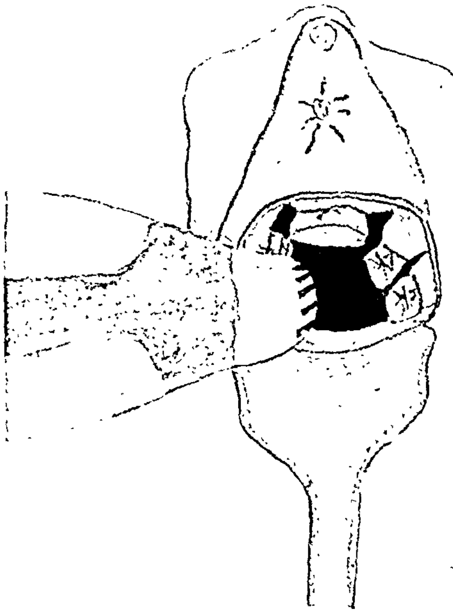

Fig. 2.—Ligature applied close to uterus.

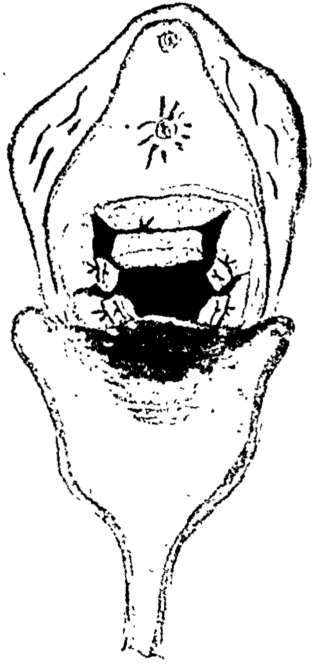

Fig. 3.—Showing stumps.

Large fibroid tumors, or small fibroids situated high up in the pelvis, should always be attacked from above.

The abdomen should always be opened when there is a well-grounded suspicion that other pathologic conditions higher up in the pelvis require attention.

TECHNIC

In all operative technic the patient's resistance must be carefully guarded by reducing traumatism to a minimum and by never exposing the patient to unnecessary waste of time. The technic of vaginal hysterectomy complies beautifully with these two conditions. Little traumatism is inflicted, there is no handling of the intestines and the work can be speedily completed.

The patient should be prepared as for abdominal section. In addition, the vaginal and the vulvovaginal surfaces should be thoroughly scrubbed and disinfected. The extreme lithotomy position, with a moderate Trendelenburg posture, should be used.

If necessary, the uterine canal is curetted. The external os is closed by sutures in all cases, and the perineum is retracted with a broad weight speculum. It is not necessary that the assistant make traction on this speculum. Two short lateral retractors and one anterior retractor are used. The cervix is seized with a strong vulsellum forceps. The customary circular incision is made completely surrounding the cervix about half an inch from the external os. In cases of complete prolapse with protrusion of the vaginal wall, urethrocele and cystocele, particular caution should be observed not to injure the displaced bladder by the first incision. The loose cervicovaginal tissue is then peeled away from the cervix toward the fundus by using the finger covered with gauze or some blunt instrument; an occasional nip of the scissors is necessary to expedite this work. The uterus is hugged closely in this operation. All bleeding points are clamped and the operative field kept clean.

When the cuff is about an inch wide the pouch of Douglas is entered close to the posterior surface of the uterus. In entering the peritoneal cavity the field should be kept clean and the surgeon should make no undue haste, as the peritoneum will sometimes simply strip up on the posterior surface of the uterus instead of tearing, and may thus confuse the operator. Once the peritoneum is incised, it is torn laterally. If a loop of intestine presents, a gauze sponge is introduced. The bladder should not be separated from the uterus at its vagino-uterine juncture at this stage, but by using the left finger as a hook the surgeon should hook up as much of the left broad ligament as convenient (Fig. 1). By making moderate traction the comparatively freed uterus will now come easily forward, and it should be tilted to the left. The tip of the left finger can easily be seen through the glistening broad ligament now tense. The surgeon must make sure that he is out of the way of the ureters. The broad ligament is perforated as close to the uterus as conditions permit, and a catgut ligature is applied *en masse*. A transfixing ligature is applied immediately in front of the first ligature. This procedure takes up but little time and will preclude all possibility of the ligature slipping. The ends of the transfixing ligatures are left long. The stump is cut close to the uterus.

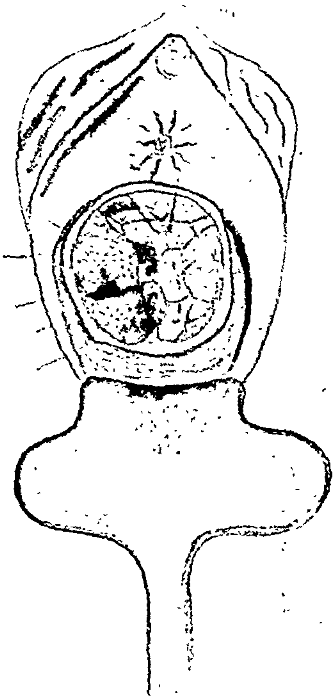

Fig. 4.—Showing arrangement of stumps to make new pelvic floor.

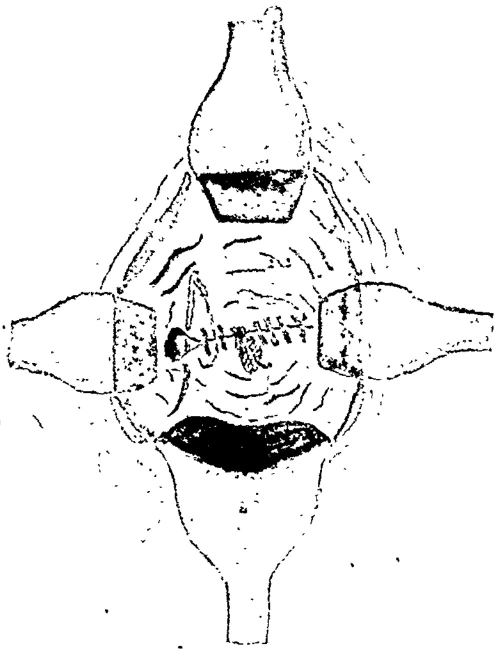

Fig. 5.—New pelvic floor.

The right side is then treated in the same manner. The left index finger is then hooked around the vesico-uterine septum. This is very easily done. The ligature is applied and cut close to the uterus, making a generous anterior stump (Fig. 2).

The uterus is now freed all round except for the two lateral upper portions of the broad ligaments.

The uterus is then delivered by seizing the fundus anteriorly. If it is impossible to do this because of the large size of the tumor, the organ must be cut in halves. There will be little or no bleeding, as the uterine arteries are both ligated while the ovarian arteries are tense and contracted. Both upper portions of the broad ligaments should be ligated, either proximally or distally, to the uterus, according to the necessity of removing or leaving behind the appendages. The stumps are transfixed and cut. All bleeding points are attended to; the field of operation cleansed, and the five, or sometimes seven, stumps are arranged (Fig. 3). The large anterior stump containing the vesicovaginal septum is placed well behind the others. The stumps are tied and sutured and thus form a new pelvic floor (Figs. 4 and 5). Should any of the stumps or even the base of the bladder look suspicious, then the ureters are located and freely dissected and all diseased parts removed. With a little patience much of the parametrium, apparently unreachable at first, can easily be brought into view. A strip of gauze introduced and the vaginal tissues and such portions of the peritoneum as can be brought up are sutured. It is necessary to pack well.

I repair the perineum if this is necessary; the procedure is simple and takes but a few minutes' additional time. Remove the gauze drain in twenty-four hours. Catheterization is usually done for three days. The patient is placed in the Fowler position, and I expect her to be up and around in ten days.

The large stump-area of anchorage of the posterior surface of the bladder, securely wedged behind the stumps of the broad ligaments now snugly retracted high in the pelvis, will overcome the cystocele effectively and permanently. I believe that anterior colporrhaphy as an adjuvant to this operation is wholly unnecessary.

REPORT OF CASES

Case 1.—Mrs. F., aged 67, had total prolapse of the uterus and vaginal wall. Urethrocele and marked cystocele were present and also small ulcers on the posterior surface of the cervix. The fundus was enlarged and the uterine canal discharged a suspicious fluid.

Operation.—Complete vaginal celiotomy. There was carcinoma of the fundus, but no glandular metastasis. Cystocele was completely overcome by this method of operation. Posterior colporrhaphy was done to correct the rectocele. The patient was discharged in two weeks and has been perfectly well since. Time elapsed since operation is fourteen months. The feeling of fulness in the vagina and bladder irritation from which the patient had suffered for twelve years, has completely left her.

Case 2.—Mrs. D., aged 78, had been suffering from cystocele and "falling of the womb" for many years. She was unable to move around much. A disagreeable sanious, vaginal discharge was present which had been getting worse of late. Operation was persistently refused until the ease of this method of operation was explained to her.

Examination.—Large cystocele was protruding and resting on the vaginal portion of the ulcerated, elongated prolapsed uterus. Marked rectocele was present. The uterus was freely movable.

Operation.—Vaginal hysterectomy. The line of reflection of the cystocele from the cervix could not be ascertained. A portion of the anterior part of the uterus which appeared healthy was taken to serve as an anterior stump to which to anchor the bladder. The technic described above was followed throughout. Perineorrhaphy was done by marginal V-incision down to the sphincters, and suturing in a perpendicular line. Time under anesthesia was fifty-two minutes. Recovery was uneventful.

The patient can now move freely about, attend to her housework, is free from all vaginal fulness and has absolutely no bladder trouble. The bladder is resting high up in the pelvis. The nurse informed me that catheterization during the first three days was difficult on account of the high position of the bladder.

CONCLUSIONS

1. Vaginal hysterectomy is only indicated in a limited class of cases. Among these I would mention cancer of the cervix, and cancer of the uterine canal in both cervix and fundus, with movable uterus; extreme prolapse of uterus and bladder; extreme retrodisplacement with metritis in women who have passed the climacteric.

2. Whenever applicable, vaginal hysterectomy has many advantages over abdominal hysterectomy, not the least of which is the avoidance of shock, and the corresponding quick recovery in elderly patients.

3. Women are singularly tolerant to operative traumatism inflicted on the pelvic organs by the vaginal route.

4. Vaginal hysterectomy has no horrors to most women suffering from cancer of the uterus, and the operation may serve us as a psychic lever to turn patients toward surgical aid in the early stages of this dreadful disease.

5. The technic of vaginal hysterectomy often presents great difficulties; but these are seldom unsurmountable.

6. Injury to the ureters, and hemorrhage, both primary and secondary, can be avoided by modern methods.

7. Cystocele and prolapse of the bowel can be completely overcome by this method.

THE PATHOLOGY OF ECLAMPSIA AND TOXEMIA OF PREGNANCY*

J. E. WELCH, M.D.
Pathologist, New York Lying-In Hospital
NEW YORK CITY.

The pathology of eclampsia is a subject that has interested the obstetrician since the beginning of his art. Before the days of postmortem research and urinary analysis the imagination of the practitioner formulated a pathology for this affection which was deduced from clinical symptoms. In the process of reasoning backward from effect to cause, few persons will follow the same course; therefore, radically different judgments are formed. Thus we have had many different explanations of the causes producing the ensemble of symptoms which have so long been called eclampsia. The chief and one essential symptom of the condition is convulsions, with which certain others may be associated in a more or less pronounced form.

Until very recently these have been required always before diagnosis should be pronounced. Even now it is an exceptionally bold diagnostician who will venture the diagnosis of eclampsia without the presence of convulsions.

Early in the era of postmortem studies in this condition, hope arose that the true explanation of the condition was at hand. Attention was largely centered on the central nervous system as the seat of the affection, since the main symptom seemed to point to that center. Changes in the brain which were given to account for the convulsions were anemia, edema, and apoplexy. These observations were very good as far as they went, but lacked in comprehensiveness.

In 1886 Jurgens by his careful labors placed the pathology of eclampsia practically in the position it now occupies. It is to him that we owe our first description of the hemorrhagic liver changes now so well known and thoroughly identified with this condition. In addition to the liver changes, he also gave an account of thrombi and liver cell emboli in the lung capillaries.

Stimulated by these findings, others devoted particular attention to the subject and as a result we have valuable contributions from Klebs, Pilliet, Lubarsch, Prutz, Gerdes, Schmorl and others who have redescribed the hepatic hemorrhages and associated them with necrosis of liver cells and thrombosis of vessels. In addition, they have shown us thrombi in other organs and emboli composed of liver and giant cells which they have described as being derived from the placenta.

The picture now accepted as typical of the pathology of eclampsia by the greater number of those familiar with the subject consists in hemorrhages in and about the portal spaces, thrombi in vessels of the liver, and giant cell emboli in other organs. These changes found postmortem in the pregnant or postpartum woman are considered by many as a justification of the diagnosis of eclampsia regardless of the presence or absence of convulsions before death. And it is with these changes in mind that the clinician will occasionally make the diagnosis of "eclampsia without convulsions."

Toxemia of pregnancy is a name obstetricians have for several years been applying to a symptom-complex characterized for the most part by headache, visual disturbances, nausea, vomiting, delirium and coma with or without edema. This group of symptoms which appears to have its origin in a more or less profound systemic poisoning, has been considered as an affection entirely apart from and independent of eclampsia because of the absence of convulsions.

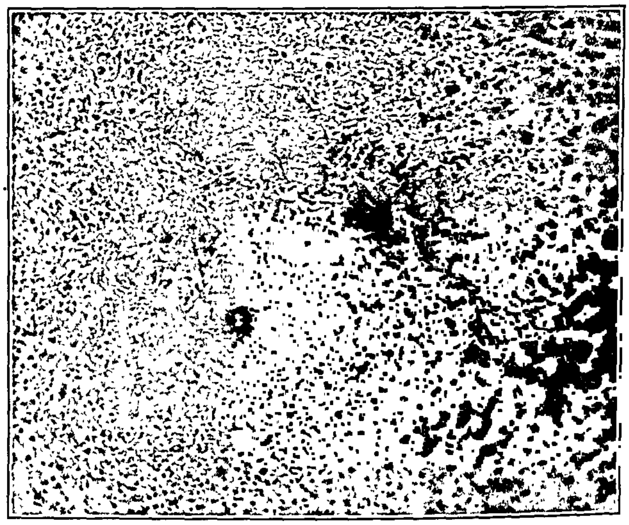

Fig. 1.—Hemorrhage in portal space.

During the development of the pathology of eclampsia by the above-named investigators, it was discovered that many pregnant and postpartum women dying from a systemic poisoning manifested by the above symptoms, with occasionally convulsions added, showed different lesions from the ones above described in connection with eclampsia. Instead of hemorrhages about the portal spaces associated with thrombi and emboli, extensive necrosis was found associated with advanced degenerative processes which when found early were limited to the central part of the liver lobule, but later invaded the remaining part of the lobule and produced a picture typical of acute yellow atrophy of the liver.

In the evolution of this subject, two sets of views have developed: one that the two conditions are entirely different diseases, eclampsia having hemorrhages about the portal spaces as its characteristic lesion and toxemia having central necrosis of the liver lobule as its characteristic lesion. The other view holds that the two conditions are different manifestations of the same disorder. Excellent contributions to both sides of the subject have been made in this country by Dr. Williams of Baltimore and Dr. James Ewing of New York.

---

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

I am presenting, in a limited way, the findings in fourteen cases which I have examined postmortem at the New York Lying-in Hospital, in the wards of which they were observed clinically. The diagnosis given in each case is that made by the clinician and not from the postmortem findings in the liver. In each case put in the class of eclampsia there were convulsions. In each case put in the class of toxemia of pregnancy there were no convulsions, but signs of systemic poisoning.

Before generalizing on the lesions found, it may be of interest to give details of the histories of four of the series, in which the most extensive hemorrhagic changes were found.

Case 3.—Eclampsia. Hemorrhages (Path. No. 887).

Patient.—Aged 21, primipara.

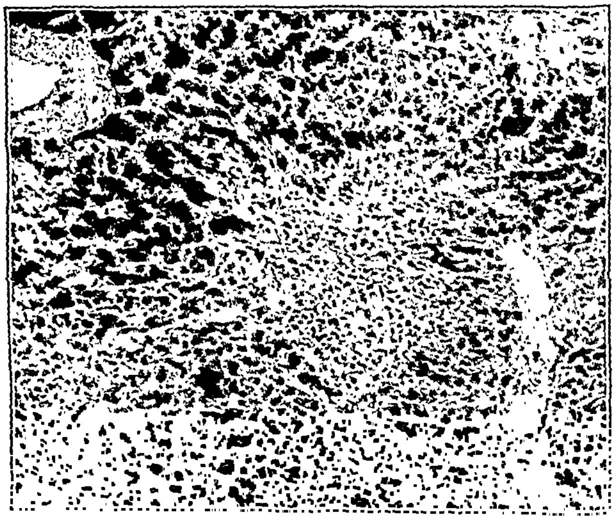

Fig. 2.—Central necrosis of liver lobule.

History.—This patient had never been ill. She had no morning sickness with present pregnancy. Five weeks before confinement she had slight morning headaches and swelling of the legs. Three weeks before confinement the headaches had stopped and the swelling diminished. There was a trace of albumin in the urine. At full term she gave birth normally to twins at 7:30 p. m., and had a comfortable evening until 11 o'clock, when she was suddenly seized by a general convulsion followed by coma, in which she died eight hours later.

Autopsy.—Body shows general edema, slight over the trunk, but marked in the feet and legs. No jaundice.

Brain: All the ventricles are filled with blood which comes from a laceration in the lower part of the pons and through the floor of the upper half of the medulla.

Liver: Weight, 2,500 grams; size is increased; color is light yellow. There are extensive hemorrhages under the capsule and through the liver substance. Microscopically, numerous hemorrhages are seen in and about the portal spaces with extensive fibrin formation. The cells show marked cloudy swelling, fatty degeneration, autolysis and pigmentation. (Fig. 1.)

Kidneys: Very much enlarged, pale and congested. Microscopically, the epithelium of the cortical tubes shows extensive degeneration and disintegration.

Case 4.—Eclampsia. Hemorrhage (Path. No. 634, 1906).

Patient.—Aged 28, iii.-para. Eighth month of gestation.

History.—She had had two previous normal pregnancies and labors. During the last previous pregnancy she had slight edema of the ankles. She enjoyed good health up to the time of attack, which came suddenly at 11 a. m. as a very severe headache. She felt fairly well during the afternoon. At 11 p. m. she had a general convulsion. She was brought to the hospital two hours later in coma, in which she died four hours after admission.

Autopsy.—Body shows edema, moderate in the body, marked in feet and legs. Subcutaneous hemorrhages over trunk and arms. No jaundice.

Brain: All ventricles are filled with blood which comes from a laceration in the left corpus striatum.

Liver: This organ is small, pale, yellow, very firm. There is extensive hemorrhage beneath the capsule and through the organ. Microscopically, extensive hemorrhages are found in and around the portal spaces. Some of the hemorrhages have destroyed as much as three lobules. The parenchyma shows cloudy swelling, slight fatty degeneration and pigmentation. (Fig. 1.)

Kidneys: These organs show extensive degeneration and sloughing of the epithelium in the tubules of the cortex. There are a few subcapsular hemorrhages over the lower part of the right.

Case 9.—Toxemia of pregnancy. Hemorrhages (Path. No. 2098).

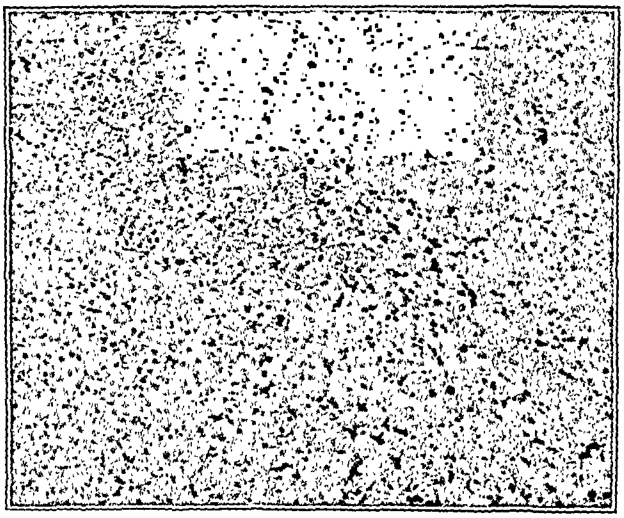

Fig. 3.—General autolysis of liver.

Patient.—Aged 30, iii.-para. Ninth month of gestation.

History.—Patient was brought to the hospital in the ambulance, having suffered from dizziness, headaches, swelling and pain in the legs for three weeks. After rest in bed and a limited diet the subjective symptoms disappeared, but the swelling of the legs persisted. She had a natural labor at 9 a. m. At 1 p. m., without having convulsions, she went into coma, which gradually deepened until 5:30 p. m., when she died.

Autopsy.—Body shows slight general edema. No jaundice.

Brain: The ventricles are all filled with fluid and clotted blood. The hemorrhage comes from a superficial laceration in the floor of the left lateral ventricle between the caudate nucleus and optic thalamus.

Liver: Slightly enlarged and light yellow. There are extensive hemorrhages beneath the capsule and through the organ. Microscopically, large hemorrhages are found in and about the portal spaces. There is very little coagulation of the blood in the hemorrhages. The liver cells in and about the hemorrhages show destruction from pressure, degeneration and necrosis. The general parenchyma is distorted and shows granular and fatty degeneration and pigmentation. About some of the hemorrhages are large accumulations of leucocytes. (Fig. 1.)

Kidneys: Are increased in size and congested. There is extensive degeneration and sloughing of the epithelium in the tubules of the cortex.

CASE 11.—Toxemia of pregnancy. Hemorrhages (Path. No. 425, 1909).

Patient.—Aged 30; iv.-para. Seven months pregnant. She was comatose when admitted; pupils were contracted; patient was generally cyanosed; there were no convulsions. Anterior lip of cervix was incised and the child delivered by internal podalic version. Patient died on day of operation.

Autopsy.—Body was not edematous. There is slight edema of the feet and legs. No jaundice.

Brain: The brain is symmetrical and well-developed. The convolutions are flattened. All the ventricles are filled with fluid blood. There is a hemorrhage in the pons which has ruptured through the floor of the upper half of the fourth ventricle.

Liver: This organ is slightly increased in size and is pale grayish yellow in color. There is extensive hemorrhage beneath the capsule and through the liver substance. Microscopically, the liver cells show cloudy swelling, hydropic and fatty degeneration. There is a large amount of bile pigment scattered through the cells. Many of the portal spaces show extensive hemorrhage in and about them with extensive fibrin formation. (Fig. 1.)

Kidneys: These organs are much increased in size. The cortices are swollen and the capsules strip easily. Microscopically, the parenchyma shows albuminous degeneration and extensive sloughing. (Fig. 5.)

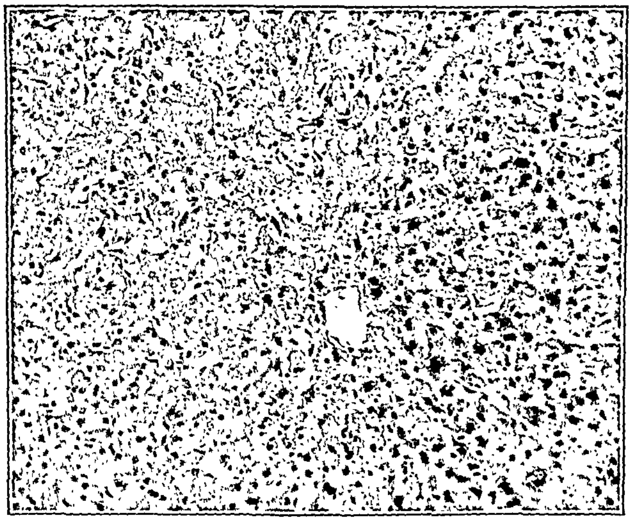

Fig. 4.—Cloudy swelling of liver.

The diagnosis of eclampsia was made in two of these cases—Cases 3 and 4—because of the convulsions before death, and toxemia of pregnancy in the other two because of the absence of convulsions, yet the lesions in the brains and livers are very similar.

The accompanying table shows that the diagnosis of eclampsia was made in ten cases. In four of these, hemorrhages occurred in the portal spaces of the liver, in three central necrosis in the liver lobules, in one a general autolysis of the liver cells, and in two cloudy swelling only. The brain in one case showed congestion only, in two cases congestion and edema, in one edema and in two hemorrhages.

Four cases of this series were classified as toxemia of pregnancy. The livers in three of these cases showed the hemorrhagic changes above described; one showed necrosis about the centers of the liver lobules. The brain in one case showed congestion, and two showed hemorrhages. The kidney lesion in all these cases was very similar and consists in a parenchymatous nephritis with extensive sloughing of the epithelium.

In addition to the liver, brain and kidney lesions the greater number of the cases showed edema, fluid in one or more of the serous cavities, small hemorrhages in the serous and mucous membranes, especially in the pulmonary pleura, visceral pericardium and in the gastric mucosa. In some of the cases there were small hemorrhages into the lung parenchyma. The heart muscle showed a slight clouding. One case exhibited subcutaneous hemorrhages and three jaundice.

It is the custom for many observers to classify eclampsia into a nephritic and a hepatic type, the former having edema in very pronounced form and the latter having jaundice present. In this series of fourteen cases only three of the patients had jaundice, and two of these had central necrosis in the liver lobules, and the third a slight cloudy swelling in the liver. Ten of the cases showing marked hemorrhagic liver changes showed no icterus. It would seem from these findings that the above classification is a very inaccurate one.

Turning to the etiology of the hemorrhages, we find them explained by the hyaline blood plate thrombi and emboli formed from cells from the liver and giant cells from the placenta. In these cases I have been unable to find the emboli of liver and placental cells, but thrombi are rather numerous, formed occasionally from blood plates, but more commonly from the fused stromas of red blood cells. It is the rule to find considerable hemolysis in the hemorrhagic cases. In some the effusions of serum in the serous cavities is deeply tinged with the diffused blood pigment. Hemolysis when occurring in the living body is usually preceded by an agglutination of the cells which undergo dissolution. It is these agglutinated cells that form the majority of the thrombi about which hemorrhages occur. Another factor in the production of the hemorrhages and probably the most important is a solution of the endothelial lining of the blood vessels. The agent causing hemolysis and cell destruction in the various organs destroys also the endothelium of the vessels, thus allowing an easy escape of the blood. Increase in blood pressure, which is usually heightened in this condition, increases the hemorrhage and gives the extensive lesions found in the brain and liver.

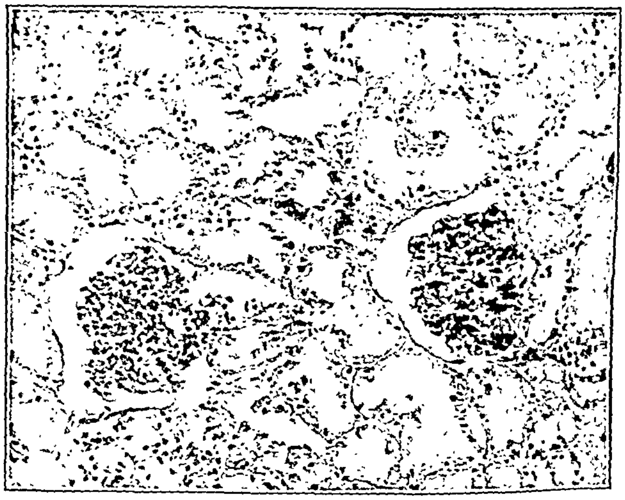

Fig. 5.—Type of parenchymatous nephritis found in all cases of eclampsia

The nature of the agent causing such general cell destruction is not definitely known. Judging from the histologic appearances of the cells affected it is probably an enzyme; but whether native in the cell with its function perverted to produce autolysis or whether introduced from a foreign source (placenta or fetus) is not determined.

The thyroid gland in these cases showed hypertrophy, and in one case considerable colloid cystic degeneration.

Studies of blood pressure in fifteen cases of eclampsia not included in this series showed a blood pressure ranging between 130 and 190. The pressure varied considerably at different times, and as a rule an increase was noted before and a decrease after the convulsive seizures.

The coagulation time was usually normal. In one case it was delayed ten minutes. No change from the normal was noted in the alkalinity. The specific gravity varied from 1035 to 1055, the lower figure was found in a patient having 52 per cent. hemoglobin. The red blood cells in these cases numbered 3,000,000 and under to each cubic millimeter of blood, except in one patient, who had 4,100,000.

The hemoglobin ranged between 52 and 60 per cent. One case showed 70 per cent. The leucocytes varied between 10,000 and 14,000. One case had 19,000. The polymorphonuclear forms varied from 79 to 81 per cent. except in one case in which there were 90 per cent.

The power of the serum of eclamptics and those suffering from toxemia of pregnancy to destroy the red cells of normal subjects was tested in fifteen cases. The serum was added to red cells of normal persons after washing the latter in 0.85 per cent. salt solution. It was found that some of the serum of each class would hemolyze normal red cells, while others would not. The cells of normal postpartum women were at first used. It was thought that pregnancy might possibly confer immunity against the action of the eclamptic hemolysin, and with this possibility in view normal male red cells were used. They were, however, found no more susceptible than the cells from postpartum women. The hemolytic power of the cerebrospinal fluid was also tested, but found invariably negative.

The urine of all the patients showed albumin, six had acetone and a marked excess of indican; two had diacetic acid and all showed casts.

The changes in the placenta when found consisted of hemorrhagic infarcts, degenerated epithelium and hyaline metamorphosis. Many placentæ show no change at all.

We are now in a position to explain some of the symptoms of these two conditions. The headaches are due to intracranial disturbance. The dura mater receives a nerve supply from the fifth cranial pair and is sensitive to cerebral changes, especially those that produce pressure. We have in these cases congestion, edema and hemorrhage which could act as irritants to the dura mater and produce the headache.

The visual disturbances, such as spots before the eyes, cloudy vision and complete blindness, are due to circulatory disturbance and edema about the base of the brain. The ophthalmoscope shows a pallor of the optic nerve, but as a rule no lesion even in the patients who have complete blindness and recover.

The petechiæ in the skin are produced by small hemorrhages from small vessels in which thrombi have formed, emboli lodged, or in which the endothelium has been destroyed. The nausea and vomiting may be due to one or a combination of causes which may be central or peripheral. The vomiting center may be impressed by poisonous substances circulating in the blood. The peripheral causes are reflex and may be due to the uterine enlargement, bowel disturbance, or to the irritation of the gastric mucosa by elimination of poisonous substances into the stomach.

Edema is produced by one or a combination of three conditions, which are: an alteration in the blood, an alteration in the vessel wall or a change in the blood pressure. In these cases there is anemia, destruction of the vascular endothelium and heightened blood pressure.

The jaundice is probably produced by cloudy swelling of the liver cells which compress the bile capillaries and increase the pressure of bile within them above that of the surrounding vessels and an overflow takes place into the blood and lymph capillaries through which the bile pigments are distributed to the tissues.

CONCLUSIONS

1. The liver lesions in eclampsia are not uniform. Pregnant or postpartum women dying from convulsions may have hemorrhages, central necrosis, general autolysis or cloudy swelling in the liver.

2. The liver lesions in toxemia of pregnancy are not uniform. They may be either hemorrhagic or central necroses, both of which are found in eclampsia.

3. The hemorrhagic lesions are produced by liver and placental cell emboli, thrombi *formed from blood plates* and fused red blood cells and by a solution of vascular endothelium. Heightened blood pressure increases the extent of the hemorrhages.

4. The agent producing the hemolysis and general cell destruction is probably an enzyme.

204 West Seventieth Street.

Itching.—C. H. Bangs, in the *Archives of Diagnosis*, July, 1909, states that itching is so common a symptom of skin affections and one so frequently associated with severe constitutional diseases that the looseness of its definition is surprising. Many text-books make no attempt to define it. He discusses the causes of itching and concludes that: 1. Itching is a manifestation of disturbed nerve function. 2. It is a sensation due to the irritation of the sensory nerves by some irritant not sufficient to produce pain. 3. The source of this irritation may be from within or without. 4. The irritation if continued or increased may, and frequently does, produce stinging, burning or pain. 5. While heat, redness, swelling and pain are the cardinal symptoms of inflammation in general, the usual combination of symptoms in dermatitis is heat, redness, swelling, together with itching, which latter is the clinical equivalent of pain.

A STUDY OF ECLAMPSIA

WITH THE RESULTS IN TWO HUNDRED AND FIFTY CASES, FROM THE WARDS OF THE LYING-IN HOSPITAL OF THE CITY OF NEW YORK*

ROSS McPHERSON, M.D.
NEW YORK CITY

There is probably no obstetric complication about which more has been written and less really understood than the condition known as eclampsia. Not knowing its cause, we have been groping blindly in the dark to secure a satisfactory treatment, which, up to the present time, has been mostly empirical and anything but satisfactory in its results.

The mortality, both maternal and fetal, is appalling, and the multiplicity of treatments recommended by physicians give testimony to the worthlessness of these methods of procedure, as the large majority have been of necessity directed toward abating the symptoms and not to relieving the cause of the difficulty.

The uncertainty which we feel about eclampsia begins with its very name. In the latest edition of Webster's dictionary it is stated that eclampsia is derived from the Greek *"eclampain,"* meaning "to shine out," and is defined as "a fancied perception of flashes of light, or convulsions; the term is usually restricted to a convulsive affection occurring during the pregnant state and parturition." On the other hand, the author of one of the well known text-books on obstetrics states that the disease was so named on account of the suddenness of its onset, coming on like a flash.

Some observers discard the use of the word "eclampsia" altogether, asserting that, as the condition is a toxemia, which sometimes occurs without convulsions, in eclampsia without convulsions—if we use the term—we have the paradoxic condition of "convulsions without convulsions." Since we realize that several kinds of toxemia probably occur during the pregnant state, it seems preferable to me to consider eclampsia as a toxemia of the convulsive type, and the cases reported in this paper will be limited to those in which one or more convulsions were actually present.

Harrar,[1] in discussing eclampsia, states that beginning with February, the number of cases increases during March, reaches the highest point in April, and then steadily diminishes, finding the lowest level in November. The curve of this rise and fall nearly corresponds to the curve of the rainfall, which fact, he states, might explain the well-known theory that climatic conditions have something to do with the disease; although it is not clear why periods of unsettled weather should have the effect of producing a convulsive toxemia in pregnant women. It is an interesting observation, however, and in the series of cases here reported the greatest number occurred in February and March, and the least in December and January, which is approximately the same as above mentioned.

Regarding the frequency of the condition, the 250 cases occurred in 14,899 labors, which means 1 case to every 60 labors (1 to 60) or 1.7 per cent. of all labors. This is a high percentage and is due to the fact that a hospital is the clearing house for so many of the cases occurring in the city, and the probability is that it is about eighteen times as frequent in hospital as in private practice, the basis for this statement being that in our out-patient department, which represents private practice, in 46,252 cases, eclampsia was encountered 43 times; that is, 1 case in every 1,075 labors, or 0.09 per cent., as opposed to 1 case in every 60 labors in the wards of the hospital or 1.7 per cent.

The condition is almost twice as common in primiparæ as in multiparæ, being 64.4 per cent. in the former and 35.6 per cent. in the latter, which proportion is more nearly equal, however, than the figures commonly given.

Multiple pregnancy is noted in this series in twelve cases, twins occurring eleven times and triplets once.

We divide eclampsia into three classes, according to whether it appears before, during or after labor; in other words, antepartum, intrapartum, and postpartum. The postpartum form is supposed to be the least common, according to the foreign observers, but in this country inspection of the literature shows that it apparently occupies second place in frequency of occurrence. In the series here reported, eclampsia was noted in the antepartum cases 140 times, or 56 per cent.; in the postpartum cases, 86 times, or 34.4 per cent., and in the intrapartum cases, 24 times, or 9.6 per cent., which agrees with the statement just made.

Regarding the age of the patients, the youngest noted was 15 and the oldest 48 years of age, the greatest number of cases occurring between the ages of 20 and 25, which is in accord with the fact that the greatest number of eclampsias occur in primiparæ.

In the natural order of discussion, in a general paper of this sort, the pathology of the condition should next be taken up, but as Dr. Welch's paper is devoted to pathology alone, and as his material was gathered largely from the cases comprising this series, and is so complete, I shall say nothing further regarding it, nor the symptoms, which are familiar to all, but after a few remarks on prognosis shall pass on to treatment.

The maternal mortality of eclampsia is given by various authors as ranging from 5 to 50 per cent. It also varies according as the treatment is expectant or immediately operative, and is, of course, much higher in hospitals than in the private practice of those who are skilled in handling the condition, as so many of the hospital patients reach the institution in a moribund state after delay and mishandling outside.

The fetal mortality is usually from 33 to 50 per cent.

In the cases here reported there were 77 maternal deaths and 110 still-born children, or those who died soon after birth, a mortality of 30.8 and 44 per cent., respectively, the latter fetal mortality being slightly below the average. Of the maternal deaths, 62.3 per cent. occurred in cases in which the eclamptic seizure took place antepartum; 31.1 per cent. in postpartum cases, and 7.7 per cent. in the intrapartum cases. On the other hand, contrasting these figures with those of our out-patient department, we find that of the 43 eclampsias there occurring, and already referred to, 10 of the patients died, a mortality of only 23 per cent., and this I must ask you to remember took place in tenement houses of the lowest type, surrounded by the most unfavorable conditions.

The treatment must be divided into (a) prophylactic and (b) curative, according to whether the patient shows symptoms of an impending attack or whether the convulsions have actually occurred, for the two conditions differ widely and yet are often treated in the same manner; we are continually seeing cases in which the proper treatment given at the right time would undoubtedly have resulted in the mother's recovery. Given a case in which headaches, dizziness, edema, and faulty elimination are present, even though no convulsions have occurred, and the patient is perfectly conscious and about the house, it is our duty to be on guard, ready to interfere promptly if the convulsive seizures supervene. Most certainly we should take all possible means to aid elimination by the various channels, in order to lighten the burden of the already overloaded organs; but if the case is growing progressively worse, and even one convulsion occurs, let us not lessen the chances for the patient by hesitating any greater length of time than is necessary to remove the cause of the difficulty, namely, the products of conception. While it is true that we do not know the exact cause of eclampsia, it is certain that the condition occurs only in the pregnant or recently pregnant state, and that every convulsion tremendously lessens the patient's chances of recovery, as the convulsions do not occur until the changes in the metabolism have gone so far that the balance between absorption and elimination has markedly increased in favor of the absorption, the eliminative organs are overpowered, and the chances for recovery decrease almost momentarily.

---

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

[1] Bull. of Lying-in Hospital of New York City, December, 1905, No. 3. p 72

In a paper entitled "A Plea for the Prompt Evacuation of the Uterus in the Treatment of Eclampsia," by Fry,[2] read before this Section in Chicago, last June, a conclusive argument is presented for early delivery, and with this view I am in hearty accord. No statistics have been adduced to show that expectant treatment is of avail, and all of us have many times seen cases in which a prompt and early interference would undoubtedly have saved the woman's life.

When a convulsion occurs, then, let us empty the uterus, without delay. The means by which this shall be done will vary somewhat with the experience and preference of the operator.

In this series delivery was accomplished, by manual dilatation and internal podalic version in 89 cases, by forceps—high and low—in 49 cases, by craniotomy in 14 cases, by abdominal Cesarean section in 10 cases, and by vaginal Cesarean section in 2 cases. Induction of labor by means of the bags of Champetier de Ribes was performed 7 times. The maternal mortality following version was 38.5 per cent.; forceps deliveries, 20.5 per cent.; induction of labor, 42.8 per cent.; craniotomy, 28.5 per cent., and Cesarean section, 40 per cent.

The fetal mortality in the operative cases after internal podalic version was 62.9 per cent.; after high forceps, 44.4 per cent.; after induction of labor, 28.5 per cent.; after abdominal Cesarean section, none at all, or 100 per cent. of living children.

These are the statistics of the 250 cases. I will not attempt a comparison of these figures, which are approximately the same as those of other authors. I wish to reiterate, however, that these high mortality figures are not entirely due to eclampsia, but rather to the delay in sending the cases to the hospital where proper treatment could be instituted, thus losing valuable time.

Concerning the actual operative procedures for delivery, I shall say nothing except in regard to Cesarean section, both abdominal and vaginal. Of the abdominal sections here reported, 8 were done for contracted pelvis in patients in whom the eclampsia was an incident; 2 were done in moribund patients for the purpose of saving the child. As I stated in a paper on Cesarean section, read in this Section last year, I believe that there are cases, such, for example, as that of an elderly primipara with a small, narrow vagina, and a long cervix with a tough unyielding os, in which a rapid Cesarean section is the operation of choice, and during the past year I have found no reason to change my opinion.

I desire to utter a word or two of caution in regard to the employment of vaginal Cesarean section; it is an operation which requires considerable technical skill, and, while it has a distinct place in obstetric surgery, the wholesale use of it which is being recommended at present is, in my opinion, entirely unwarrantable. Any operation which offers the risks of puncturing the bladder and rectum—and I have seen this done by competent operators—the dangers of hemorrhage and the difficulties of suture which this one does, is not lightly to be undertaken, except in the hands of an experienced vaginal operator, under exceptional circumstances, and even he may at times meet with great difficulties in securing a satisfactory outcome to his case.

Finally, when the patient is delivered, the uterus emptied, and convulsions then either continue or come on, this is the time when efforts should be directed first toward controlling the convulsions, in order that the patient may not do herself bodily injury, and, second, toward securing elimination by the various excretory channels of the body.

To control convulsions, for a long time chloroform has been used most generally. In addition to this, bromids and chloral by rectum, morphin and other hypnotics have been tried. For the past few years, however, I have been using scopolamin hydrobromate, gr. 1/100, in combination with morphin sulphate, gr. 1/6, and have been highly pleased with the results, which have been most satisfactory. One or two doses generally suffice, and the amount of morphin given is not sufficient to lock up the bowels, which is the objection usually lodged against it. It is to be remembered, however, that the changes in the organs have here advanced so far that they are not doing their excretory work properly, and so the main attention should be turned toward elimination. This is accomplished by rectal irrigations of normal saline solution in large quantities, by bleeding followed by intravenous infusions of normal salt solution, hot packs and as free catharsis as possible. Thyroid extract has been tried with apparent promise, and in some parts of the country veratrum viride is still high in favor.

In closing, allow me to emphasize that—until we have a more tangible knowledge of the actual cause of these toxemic convulsions—the only feasible treatment for the condition of eclampsia is immediate evacuation of the uterine contents, *followed* by proper eliminative care in the puerperium.

37 Madison Avenue.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. WELCH AND M'PHERSON

Dr. Horace G. Wetherill, Denver: I read a paper on subject allied to this at the Chicago Session last year. I saw in the pathologic collection the livers and brains from the cases reported by Dr. Welch, and they are characteristic of similar cases which I have seen. There are one or two points in which my judgment would not confirm the statements made in the papers, particularly in the paper of Dr. Welch. He says that usually the ophthalmoscope shows very little. In the cases I have had an opportunity to observe the ophthalmoscope has been of the greatest possible assistance. Early in the disease, and before many of the general symptoms were developed, there were very definite changes in the eye-grounds in the form of a neuroretinitis or even small retinal hemorrhages, and I have learned to think that the oculist may be of great service in making early diagnoses in these cases. I can not agree either with the statement made with reference to the use of chloroform. We know that the cases of late chloroform poisoning present pathologic changes closely allied to those which Dr. Welch has shown us in drawings, and in my opinion it is not at all safe or wise to give chloroform to patients under these circumstances. That is a point which I tried to make clear in my paper last year, and which my previous observation and subsequent experience lead me to believe is a very important one.

---

[2] The Journal A. M. A., Dec. 12, 1908, li, 2041.

Dr. F. Lawrence, Columbus: I wish to report briefly two recent observations, for what they may be worth in the matter of etiology or causation, and possibly for the help they may give in future observations. One patient was a young woman, a primipara, under the care of an excellent physician. There was marked anemia, on account of which a blood-count was made by a pathologist. The hemoglobin test revealed between 30 and 40, about 2,000,000 and a fraction under 3,000,000 reds, with approximately a normal count of about 4,500 white corpuscles. There was at the first observation very little albumin, but in the course of perhaps ten days there was a further marked diminution in hemoglobin and in the red blood-count, with approximately a level white blood-count. The albumin markedly increased and the woman died in an eclamptic seizure. The other patient was a young woman who a year before aborted with twins at about the fifth month. She had a marked amount of albumin and was anemic. She was taken to the hospital, where the blood-count showed 2,100,000 reds, 4,200 whites and 31 hemoglobin. She was placed under the charge of my colleague, Dr. Whitaker, and he treated her by the usual remedies and by forced feeding to increase the blood count and the hemoglobin, but without effect. She was near term, and was delivered naturally and without convulsions. About twenty-two hours afterward she died like a flash. She had a marked amount of albumin. The question in my mind is, how much can we do by more careful blood observation to prevent these unfortunate deaths? How much can we do by educating not only the physician, but the patient that the woman who is to become a mother should have all the careful observation in the early stages of pregnancy that is given in any other crisis of life? It seems to me that we should accomplish something in this matter by an exhaustive study of the blood conditions.

Dr. C. C. Frederick, Buffalo: I wish to relate an experience that I recently had which might possibly be of interest. In January or February I read a paper in Detroit before the Wayne County Medical Society. At a little informal gathering after the meeting the subject of tetanus came up for discussion, and Dr. Hutchins of Detroit spoke of the control of the convulsions of tetanus by the administration of "chloretone," and told me that he had succeeded in controlling convulsions in five cases of tetanus out of six through to recovery. This is an unusual percentage, and he ascribed his success largely to the chloretone as an antispasmodic. It occurred to me that possibly this drug might be of benefit in puerperal eclampsia because if the eclamptic seizures in the ordinary run of cases can be controlled by any means whatsoever, without detriment to the patient, the patient may be carried along until by elimination the toxemia is got rid of and the convulsions cease. I agree with those who oppose the use of chloroform because, as stated, we know that the late poisonous effects of chloroform are very similar to the results of toxemia. I have seen two cases in consultation, in both of which I advised the use of chloretone as an antispasmodic, and I was much pleased with the effects. It is given by rectum if the patient is unable to swallow. If the patient can swallow, 10 or 15 grains are administered in water. I carried both these patients along with the chloretone for twenty-four and thirty-six hours, respectively, until they were rid of the toxemia.

Dr. C. S. Bacon, Chicago: I wish to call attention particularly to the nature of the disease that precedes the convulsions. It seems to me that it is an advantage for us to look on eclamptogenic disease, the pre-eclamptic stage, as a disease, one symptom of which is convulsions. Looking on it in this way we regard the convulsions simply as the crisis, as we regard infantile convulsions as the crisis of an intestinal infection. The question is then the study of this eclamptogenic disease and here, of course, the pathology as discussed in the paper of Dr. Welch is of the utmost importance. But the question of diagnosis before the convulsion occurs is also of importance. We have all had the experience that the study of the urine fails us. Sometimes convulsions occur when there has been no albumin up to within a few hours of the convulsions. The eye symptoms fail. Other symptoms fail. I have long regarded general edema as one of the most important of the symptoms of this disease. In the last two years I have begun to make regular investigations of the blood-pressure in all patients, and so far my experience leads me to think that the systematic study of the blood-pressure is one of the best means at our command. I have not yet seen any convulsions in cases in which the blood-pressure is not above 160. In most instances, as recorded by the ordinary instruments, the pressure has been in the neighborhood of 180 or above. I believe, therefore, this is a very important point in the diagnosis and the prognosis of the disease. It is also of great value in the diagnosis of eclampsia. I have had two cases this year in which the convulsions were diagnosed as eclamptic, but were shown afterward not to be eclamptic. One patient was hysterical, the other was an old epileptic. In both cases eclampsia was doubted because of the low blood-pressure. In general, this would perhaps be of great value in enabling us early to determine this disease and prevent the climax. We know that the results of treatment are very unsatisfactory. The result given by Dr. Welch shows 30 *per cent.* of maternal deaths. Everything points to the necessity for increased knowledge of the disease and our hope is in a future determination of its character.

This, however, does not carry us very far along toward treatment. Everything that we can do to prevent the occurrence of convulsions we should do. Interference with the high blood-pressure is of value. The induction of labor I believe is of the utmost importance. Up to the last year I have been favorable to the vaginal Cesarean section, but one or two bad experiences of my own, and others reported by other operators in my own town have led me to the same conclusion as that expressed by Dr. McPherson, namely, that the method is dangerous. Undoubtedly the dilatation of the cervix in proper cases is the correct method to pursue with delivery by forceps or otherwise if the cervix is thoroughly dilated but in a rigid cervix the abdominal section is quicker and safer than the vaginal.

Dr. Henry D. Fry, Washington, D. C.: I am gratified to find that Dr. McPherson bears out the line of treatment that I suggested in the paper I read last year before this Section in Chicago. I think that the only way to treat eclampsia until we know something about the cause of it is to treat it in the same way that we treat placenta prævia. In some cases there is a dangerous condition, the result of the fetus in the uterus, the mother is liable to die of hemorrhage, and the only safety to the woman is to empty the uterus at once. In other cases there is a toxemic condition coming on and if we delay by using any treatment other than immediate evacuation of the uterus we are losing valuable time. I am sorry to have Dr. Fredericks recommend chloretone. It may be a good thing, but we have done too much in this line of trying to hold back the convulsions by the use of antispasmodics. The only good statistics to be found to-day of the treatment of eclampsia, the only ones giving a mortality under 10 per cent. are those given as a result of emptying the uterus at once, and no other. If the obstetrician dilly dallies, treats with diaphoretics, etc., to control the convulsions, he is losing valuable time. Dr. McPherson showed that the mortality is highest in the antepartum cases. This is because of the delay; because the uterus is not emptied soon enough. The statistics which he gives of the high death rate after the birth of the child is contrary to many of our text-books, which state that in the most favorable cases the mortality is only 7 per cent. I believe the mortality is higher and that the reason that these women who die in the post-partum stage do not die from the primary toxic condition but from a secondary condition, is a complication involving not only the mother's liver but the brain. The brain shows intracranial hemorrhage, and I think these women who die in what we call eclampsia postpartum, die of secondary conditions, the result of letting the convulsions continue too long. The indication is therefore to empty the uterus at once. The text-books are very conservative on eclampsia. They first state what to do to eliminate the poison; next, to control the convulsions, and last, they tell about the obstetric treatment, but they do not urge the quick and prompt evacuation of the uterus.

If that is the line of treatment the next question is how best to empty the uterus. In cases in which labor has advanced and the cervix is dilated, it is easy to apply forceps after rupturing the membranes. The larger number of cases of eclampsia we have and the worst cases are those in primiparæ, in whom there is an intact cervix, rigid and undilated, and in whom labor has probably not begun. Such a uterus can not be emptied quickly by manual dilatation, by the rubber bag, or by the Bossi dilator. Either abdominal or vaginal Cesarean section must be done. The maternal mortality in abdominal Cesarean section is high; the fetal mortality low. I want to say something in favor of vaginal Cesarean section. The operation is not popular. At the session in Chicago Dr. Carstens, in discussing my paper, said that vaginal Cesarean section was such a simple thing that every general practitioner ought to be prepared to do it. I disagreed with him and agree with what has been said to-day, that the operation should be done only by a man who does vaginal surgery; and, done by such men I think it is the most valuable obstetric practice in eclampsia in primiparæ.

Dr. C. C. Frederick, Buffalo: I do not think that Dr. Fry had any right to assume that I believe in sacrificing any patient with puerperal eclampsia simply because I recommended the use of chloretone. I feel sure that Dr. Fry would do anything to control the convulsions while he was getting the baby out of the uterus. Chloretone will do that. I take the baby out just as quickly as I can, but I believe in the use of chloretone to control the seizures.

Dr. Reuben Peterson, Ann Arbor, Mich.: I am glad to hear Dr. Fry approve of vaginal Cesarean section. I am a believer in the operation, but I disagree with him in regard to the use of this operation by the general practitioner. It is not an especially easy operation, but what under certain conditions is the practitioner going to do? When he encounters one of these cases out in the country he can not send ten, fifteen or twenty miles for a specialist. If he could do that it would be all right, but he has to meet the emergency as he finds it, and how shall he do this? Take the kind of patient Dr. Fry is speaking of, a primipara with rigid cervix. We all know what dilatation of the cervix under these conditions means. The practitioner begins before breakfast, goes home to lunch, returns and continues the dilatation, and then finally, after having infected his patient, delivers her. Given such a condition, what operation will do the least damage? I maintain that the general practitioner under such conditions will do the least damage by doing a vaginal Cesarean section rather than manual dilatation. The only other operation is dilatation with the Bossi instrument, the use of which will do far more damage than the vaginal Cesarean section. The latter operation is one which the general practitioner need not hesitate to peform, for the life of the woman depends on emptying the uterus quickly and I firmly believe that that is the proper treatment in eclampsia. He makes an incision anteriorly or posteriorly, as the case may be. He pushes up the bladder, splits the cervix and delivers by version. Vaginal Cesarean section is a much simpler operation than high-forceps delivery, yet the high-forceps operation is thought perfectly proper for the general practitioner to do. In our schools the students are taught to do this dangerous operation, and yet when it comes to a much simpler operation, splitting the cervix from below, the practitioner is told that he should not do it. I am not a believer in indiscriminate operating by the general practitioner, but when the emergency arises and he has to empty the uterus, he will do this with better results by the vaginal Cesarean section than by manual dilatation.

Dr. J. E. Welch, New York: In the diagnosis of eclampsia by examination with the ophthalmoscope, the examinations were made in a number of cases, not by me or any one inexperienced in the use of the ophthalmoscope, but by no less an authority than Dr. Arnold Knapp. I have his word for these changes. Of course pregnant women dying of convulsions may have hemorrhages in the background of the eye. These patients may be suffering from nephritis as a primary disease in which hemorrhages are not uncommon. It is possible for the convulsions to be produced by other conditions than those which cause the liver changes mentioned. As to bacteria being the cause of eclampsia I can say, after making many blood cultures, that I have never found it so.

I did not mean to give the impression that autolysis occurred in one case only. In the section marked autolysis, the cells are very much enlarged and retain their outline, but the protoplasm appears to have been dissolved. One liver showed this condition throughout and it can be found in nearly all the cases in isolated cells. Women dying of convulsions often do not show these advanced liver changes, and again others dying without convulsions may show them; from which we may assume that the convulsions are not always produced by the liver lesions.

The urine has been responsible for induction of many labors. At first it was albumin which was responsible for the induced labor, then urea. Many a man has terminated pregnancy because of a low urea percentage. Then the nitrogen and the high ammonia content came in for attention. These changes only indicate a disturbed metabolism and are found in conditions other than pregnancy, and from which recovery often takes place. No one of these things can be depended on as an absolute criterion. The finding of leucin and tyrosin is most unsatisfactory. Their presence cannot be determined by the microscope, for crystals resembling them often, when submitted to some more ultimate test, prove to be a different composition. The blood pressure in these cases is usually high. Some patients will have convulsions when the pressure is below 160. We are now familiar with the pathology of eclampsia from the standpoint of morphology, but we are in need of some certain means of diagnosis to determine which patients are in danger and which not.

The obstetrician should be one of the broadest men in the profession of medicine and able to study his case from all possible standpoints. Usually it is the young man recently out of college to whom the older practitioner turns his obstetric cases. The greatest evil comes through the midwife who is untrained and cannot recognize the danger signals in this condition. This Section of the American Medical Association ought to take some action toward limiting the practice of midwives. In these cases the lives of two persons are endangered, and since we find no one pathologic condition that will tell us which is the dangerous case and which is not, the obstetrician should be thoroughly trained in the interpretation of clinical signs both by the bedside and through the laboratory.

Dr. Ross McPherson, New York City: I think I stated in my paper that chloroform was used. Dr. Wetherill thought I advocated the use of it. It was because I objected to its use that I tried to get something else and began the use of scopolamin in the doses of which I spoke. I do not think scopolamin can be trifled with indiscriminately, and I am inclined to think that the dangers of chloroform are over-rated, because there is so much of it used without any apparent trouble. However, the lesions that one does find posmortem, agree with the excessive use of chloroform. I do not agree with Dr. Wetherill that edema is an extremely important symptom. I see many patients with an excessive amount of edema who do not have eclampsia and who recover without trouble. I admit that it is distressing to have a patient who is absolutely water-logged. I have had one or two recently who have had quite as much edema as any patients I have ever seen, with absolutely no other symptoms at all.

Regarding vaginal Cesarean section, Dr. Peterson sums up the matter very well in saying that if the obstetrician knows the technic it is not a difficult operation. But the trouble is that the general practitioner does not know the technic and has not the opportunity to get the experience. It is very simple to say, make an anterior incision in the cervix and a transverse incision in the vaginal vault and push the bladder out of the way; if not enough room, then make a posterior incision, go in and push the rectum out of the way, but it is difficult to do it. Furthermore, these patients have a way of bleeding quite extensively. I think the operation has a distinct time and place, but that the indiscriminate use of it is an extremely hazardous thing.

THE TREATMENT OF DIABETES MELLITUS*

J. RUDISCH, M.D.
Attending Physician, Mount Sinai Hospital
NEW YORK

The treatment outlined in this paper has been followed during the past two years in a number of cases of diabetes mellitus of various types; old cases in old subjects, more recent cases in younger subjects. From the experience thus gained I have been able to outline a regimen which, when adapted to the individual peculiarities and idiosyncrasies of the patient and supplemented by the administration of atropin, which I shall discuss in greater detail presently, has given very satisfactory results. The amount of sugar excreted has fallen rapidly, the patients have gained in weight, their carbohydrate tolerance has increased, their general condition has improved, they no longer ask for great quantities of food and of water, and they seem to be able to keep up their treatment over a long period without undue craving for carbohydrates.

While the majority of my patients have been adults, I shall at present consider only cases of diabetes occurring in juveniles. After a brief outline of the histories of three cases. I shall discuss the treatment under the following headings:

I. The administration of fats.

II. The presence of acetone bodies in the urine and their relation to strict protein diet.

III. The quantitative limitation of the proteins and fats.

IV. The administration of drugs.

REPORT OF CASES

CASE 1.—*Patient.*—Willie S., aged 9; no family history of diabetes. Except for measles in early childhood and a tonsillotomy three years ago he had always been well; had always had nocturnal enuresis. Present illness was of four or five months' duration. Mother had noticed an increased amount of urination, together with excessive thirst and bulimia. He was growing thinner and weaker. There had been a gradual progression of these symptoms. On admission to hospital, Oct. 15, 1908, he was passing between 4,000 and 4,500 c.c. of urine containing 250 gms. of sugar, acetone and diacetic acid. He weighed 56 pounds and was in poor physical condition.

Course of Disease Under Treatment.—He was put under the treatment I shall outline presently, and by the middle of January (three months) was sugar-free, passed between 1,500 and 2,000 c.c. of urine, weighed 61 pounds, and had lost his diacetic acid. His urine continued to show acetone until February 1. Since then, with the exception of occasional days on which he had a slight glycosuria due to his having surreptitiously obtained cakes or other forbidden foods, his urine has been free from sugar. He weighs 70 pounds. He is still under observation in the hospital.

CASE 2.—*Patient.*—Barney O., aged 11; admitted Feb. 27, 1909; discharged April 24. Father is "nervous." There was no family history of diabetes. There were three other healthy children. Mother had five miscarriages. Patient had the usual diseases of childhood. Patient, six years before admission, suffered a blow over the right eye and a fall from which he was unconscious for ten minutes. He was a nervous, sensitive child and had had nocturnal enuresis since infancy. Three months previous to admission he began to lose weight and mother noticed an increased thirst and appetite. Patient began to cough and expectorate blood (?). Weakness increased and urine was found to contain sugar. On admission he passed between 2,000 and 3,000 c.c. of urine, containing 78 gms. of sugar, acetone and diacetic acid. He weighed 73 pounds.

Course of Disease Under Treatment.—Diacetic acid disappeared in ten days under treatment. Acetone persisted for two weeks longer. He gained weight and the urine gradually lost sugar. By April 10 his urine was sugar-free and he weighed 84 pounds. The urine was still sugar-free on June 9, 1909.

CASE 3.—*Patient.*—Bertha N., aged 14; admitted Jan. 10, 1909; discharged February 26; well until present illness. No diabetes in family. Menstruation began one year before admission, regular; amenorrhea for past three months; for past two weeks the patient had noticed bulimia, excessive thirst and frequent micturition. She voided large quantities of pale clear urine; thought she had grown thinner. On admission she passed from 1,500 to 2,000 c.c. of urine containing acetone and diacetic acid and about 25 gm. of sugar. She weighed 90 pounds.

Course of Disease Under Treatment.—Diacetic acid disappeared in three days, acetone in two weeks. Sugar diminished and weight increased. On February 24 the urine was free from sugar and the patient weighed 97 pounds. She insisted on leaving the hospital. This case, as well as the preceding one, has been under my observation since leaving the hospital. The urine of both patients has remained free from sugar; their general condition is excellent.

I. ADMINISTRATION OF FATS

All authorities on diet in diabetes recommend the administration of large quantities of fat on account of its high caloric value and its easy assimilation. This is to supply the deficit in the caloric value of the food due to the withdrawal of the carbohydrates. I have found, however, that the large quantities of fat ordinarily used often cause severe digestive disturbances, such as anorexia and diarrhea, with consequent loss to the patient of all that had been gained by weeks of careful treatment. In those patients who were given only small quantities of fat nothing but good effects were observed. The sugar excretion diminished, and eventually disappeared, the patients gained weight, and felt better than those who were on a rich fat diet.

In some cases vegetable fats can be substituted for animal fats with great advantage. Olive-oil is the best form in which to administer fat, and is especially well borne by young subjects. It should be given in gradually increasing doses, from one teaspoonful to two tablespoonfuls and more after each meal.

II. ACETONE BODIES AND THEIR RELATION TO PROTEIN DIET.

The question arises whether or not we shall continue our attempt to reduce the glycosuria by the withdrawal of carbohydrates in the presence of large quantities of acetone and diacetic acid. This is the problem the practitioner is asked to face in all severer cases. He finds in the text-books that when acetone bodies appear in the urine he is immediately to add carbohydrates to the patient's diet to ward off the onset of coma. The results of my observations have led me to the conclusion that this dictum must not be applied indiscriminately, and that in very many cases of acidosis a strict protein diet is not merely not harmful but even distinctly beneficial.

The carbohydrates in severe diabetes do not enter into the patient's economy. They increase the hyperglycemia, are excreted as glucose in the urine, and often prevent but little, if at all, the formation of the acetone bodies.

When a healthy person is suddenly deprived of all carbohydrate food, acetone, above the small quantity present normally, usually appears in the urine. Diacetic and beta-oxybutyric acids also appear occasionally. All these acetone bodies will disappear in a few days, however, even though the carbohydrates continue to be withheld. In the majority of cases of diabetes, especially in those of a milder type, the same rule holds good. Most of the patients who enter the wards of Mount Sinai Hospital with diabetes show acetone, and many of them have diacetic and beta-oxybutyric acids as well. I have up to now been fortunate in never having seen a single case in which coma followed a strict protein and fat diet to the exclusion of all carbohydrates.

---

* Read in the Section on Diseases of Children of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

Those patients who have been under observation and have been kept on a strict carbohydrate free diet for some time form a different class. If they develop acetone bodies it is necessary to allow them some carbohydrates, with a corresponding diminution in proteids, until the diacetic acid diminishes or disappears. We may thus be able to prevent the onset of coma.

In the three cases whose histories I have given there were acetone and diacetic acid present on admission. The first patient was not put immediately on a rigid diet; he was given milk and a little fruit; but in the other two children even the presence of the acetone bodies did not deter us from putting them on a strict protein-fat diet, with the result that diacetic acid, acetone and sugar gradually disappeared from the urine.

III. CALORIC VALUE OF DIET

It has been held that in the ordinary metabolism of a healthy human being living on a mixed diet an amount of food averaging 35 to 40 calories per kilo of body weight is necessary to keep up the nutrition. In diabetes, therefore, when we remove the principal source of energy, the carbohydrates, fats have been used to supply the deficiency, and a diet extraordinarily rich in fat has been the rule. I may run contrary to this generally accepted rule when I say that 35 to 40 calories per kilo are more than necessary, at least in patients who are mostly at rest in bed. My contention is clearly proved by the fact that my patients not only kept up their weight, but even laid on flesh on a smaller number of calories. This observation is not unique. Naunyn mentions a case in which for several months a patient was kept on a diet averaging about 25 calories per kilo. During this time the patient gained 13 pounds in weight.

Whether this is due to the perfect rest, mostly in bed, or whether diabetics, owing to the altered metabolism, are able to use the excess of nitrogenous food to better advantage, I do not know. These are open questions to be decided, perhaps, by future investigation.

The first child was on a liberal protein and fat diet. In the early part of his stay in the hospital his diet was equivalent to about 80 calories per kilo of body weight. During this time he continued to excrete large quantities of sugar and lost weight rapidly. Later the caloric value of the diet was very much reduced by diminishing the proteids, but not the fats. On this limited diet the boy improved very rapidly.

As an example of the diet at this time we find the following:

Tomato soup..	300 gm.	Soup	300 gm.
Spinach soup..	90 gm.	Chicken	60 gm.
Pickle	30 gm.	Eggs (4)	120 gm.
Apple	180 gm.	Almonds	120 gm.
Lettuce	30 gm.	Tomato	120 gm.
Sauerkraut ...	60 gm.	Watercress soup.	150 gm.
Boiled beef....	180 gm.	Olive-oil	60 gm.

The daily diet selected from this list totalled 2,180 calories, averaging 78+ calories per kilo of body weight. Later diets were so arranged that the patient received an average of 30 calories per kilo.

The other two children were given a protein diet with no other fat than that on a little bacon (one or two ounces), and on their meat, which they preferred rather lean. They did well, gained weight, and lost their glycosuria on a diet averaging below twenty-five calories per kilo. As an example we find:

Eggs	325 gm.	Asparagus	40 gm.
Meat	100 gm.	Celery	37 gm.
Chicken	55 gm.	Pickle	70 gm.
Fish	135 gm.	Tomato	125 gm.
Spinach	77 gm.	Soup	300 gm.
Coffee	240 gm.		

A total of 750 calories averaging 21+ calories per kilo.

These diets are not specially selected but were chosen at random from the diet lists without reference to the patients' history charts.

In nearly all cases of any duration that come under my observation the patients are in the habit of taking enormous quantities of food and in some cases there is marked distention of the stomach and intestines. These patients complained of a feeling of emptiness on our reduced diets. Spinach, tomato or cabbage soup and green salads served well to fill up without disarranging their digestion or adding much carbohydrate.

After a short time, due partly to the diminution or cessation of the sugar output and partly, I am sure, to the administration of large doses of atropin, my patients lose this feeling of hunger and are content with smaller quantities.

The rule in feeding these patients is to give them as much of the prescribed food as they demand, admonishing them, however, that it is better for them to eat little. The daily diets that we have recorded do not, therefore, represent the allowance of food, but rather the amount consumed by the patient. This is an important point, as it shows the possibility of continuing a low diet over a considerable time without causing the patient to become dissatisfied with the meagerness of his fare.

IV. THE ADMINISTRATION OF DRUGS

Whenever a number of remedies are offered for the treatment of a diseased condition it is certain that they are alike in one respect, their inefficiency. There is hardly a drug that has not been tried in an attempt to diminish the glycosuria.

There are, however, three drugs to which I wish to direct attention. They are sodium bicarbonate, opium and atropin.

The use of sodium bicarbonate is usually limited to the control of acidosis. I have received the impression, however, that when given in conjunction with a carbohydrate free diet and in sufficiently large doses—30 to 40 gm. a day—it exerts a distinct inhibiting influence on the excretion of sugar. This statement has also been made by Reale. That this drug has an influence on the pancreas, the organ that is most concerned in diabetes in man, is further shown by the experiments of Pawlow on dogs and more recently by the beneficial action of sodium bicarbonate combined with strict carbohydrate free diet in the healing of pancreatic fistulas in man (Wohlgemuth).

Opium and its alkaloids, morphin and codein, enjoy a great measure of well-deserved popularity. The objections to these drugs are the danger of establishing a drug-habit and the uncertainty of their action. In some cases there is no response at all to their administration; in others as soon as the drug is stopped the glycosuria returns and much larger doses are then required in order to control the sugar excretion again.

It is in those cases in which the neurotic element is present that opium is especially valuable. One such patient, a woman, very tractable, very amenable to treatment, who had no opportunities to indulge in forbidden food, would repeatedly have attacks of depression or excitability accompanied by an increase in glycosuria. These attacks were always allayed and the amount of sugar reduced by liberal doses of codein.

It has been my good fortune to discover that atropin has a more marked influence on the sugar excretion than any of the drugs that have heretofore been tried. It has the advantage of being well borne in large doses, if given cautiously and in gradually increasing amounts. In two and a half years' clinical experience I have not found that a habit has been established in any case or that there are any bad effects on the general health from its prolonged administration.

With atropin the glycosuria disappears much more rapidly than with a carbohydrate-free diet alone. When, with the cautious increase in carbohydrates in patients whose urine has become sugar-free, sugar again appears, it is often possible to suppress the sugar excretion solely by atropin without reducing the carbohydrates. In other words, the carbohydrate tolerance is greater with atropin than without. The sulphate is the form most generally used in the wards. Methyl bromid (Merck) has certain advantages. It is much less toxic than the sulphate and is therefore safer for patients who are not under daily supervision. Its action is not as striking as that of the sulphate. The glycosuria does not disappear as rapidly nor is the limit of carbohydrate tolerance raised as soon as with the sulphate. Its expense, too, limits its use somewhat.

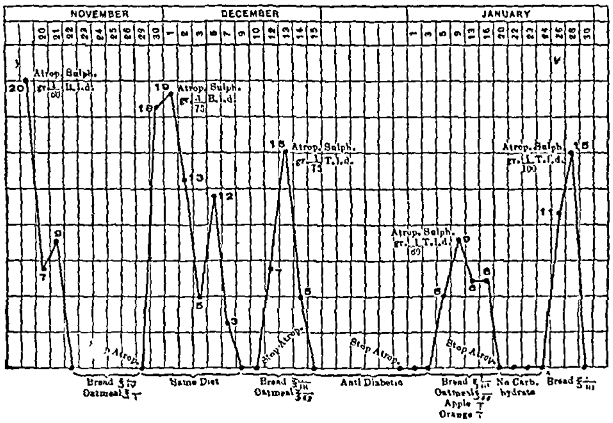

Chart showing amount of sugar (represented by isolated figures) excreted in urine of a woman of 35 under administration of atropin.

Extremely large doses of methyl bromid of atropin are well borne if given with care. I have found that an initial dose of gr. 2/15 t. i. d. can be safely used in adults and can be increased by gr. 1/15 at a time until gr. 8/15 are being given three times daily. In one instance three grains were given daily over a short period with no other disagreeable effect than dryness of the throat. In children I would advise gr. 1/60 t. i. d. as an initial dose.

With the sulphate the initial dose in adults was gr. 1/150 t. i. d. increased slowly in some cases up to gr. 1/20 t. i. d. In the nine-year-old child the initial dose was gr. 1/250 t. i. d., which was increased up to gr. 1/10 per diem. Not all of my cases required anything approaching these maximum doses. *Often a third of the maximum dose accomplished all that I wished.*

When the toxic effects were observed, a rapid pulse, flushed cheeks, dry throat and dilated pupils, I either stopped increasing the dose for a time or stopped the drug entirely. Later it was always possible to resume its administration and I was then able to give larger doses without discomfort to the patient.

In conclusion let me present graphically the effects of atropin administration, both on the reduction of sugar and on the increase in carbohydrate tolerance.

As an example I have selected the chart of a woman of 35 years, who was admitted to the hospital Nov. 19, 1906. At this time there was a daily sugar excretion of 20 gm. On a rigid antidiabetic diet, together with atropin sulphate, gr. 1/60 b. i. d., the sugar disappeared in four days. While continuing the atropin four ounces of bread and one ounce of oatmeal were added to the daily diet without the reappearance of glycosuria. On November 28 the atropin was stopped and sugar promptly appeared in the urine. On the readministration of the atropin without change in the diet the sugar gradually fell, and by December 10 it had again disappeared. Despite a partial withdrawal of carbohydrates (bread 3 ounces, and oatmeal ½ ounce) sugar now reappeared in the urine as soon as the atropin was stopped, to disappear with the resumption of the drug.

The patient was now put on a strict carbohydrate-free diet with the continuous administration of atropin for two weeks. On this diet, even when the atropin was stopped, the urine continued to be sugar-free, but on the addition of 3 ounces of bread and ½ ounce of oatmeal the sugar excretion rose promptly to 9 gm. It is, therefore, evident that a smaller amount of carbohydrates sufficed to produce glycosuria when no atropin was being administered. To exclude the possibility of coincidence the experiment was repeated, with the same result.

39 East Sixty-third Street.

ABSTRACT OF DISCUSSION

Dr. Abraham Jacobi, New York City: Diabetes, while a rare disease half a century ago, has become comparatively common. During my work in the clinic of Bonn, eighteen months of continuous service (from 1849 to 1851) furnished but a single case. At that time the disease was considered absolutely fatal. I may have seen fifteen cases in children under 12, all the patients dying and in a comparatively short time, few living more than a few months after diagnosis was made.

On the other hand, there are authors who profess to have had many recoveries. Wegeli collected 108 cases in children with 39 (!) recoveries; Külz reported 30 years ago 111 cases, with 6 recoveries; Langstein, in 1905, reported 8 cases, in 3 of which the patients recovered; Bogoraz reported 500 cases (13 patients under 1 year, 92 from 1 to 5 years, 147 from 5 to 10 years and 234 from 10 to 15 years old) with a mortality of 90 per cent. Since that time he has collected 56 more with 46 deaths. The large number of recoveries reported by some physicians has often made me doubt the diagnosis. Possibly many a case was not one of diabetes, but a pentosuria which has been differentiated only a comparatively few years, so late indeed that Janeway (*Am. Jour. Med. Sc.*, September, 1905) could not collect more than 21 cases.

The etiologic factors are various. Blumenbort believes strongly in heredity. Other causes given are neuropathy, epilepsy, insanity, heredosyphilis, injuries to, or tumors of, the brain, atrophy of the pancreas, dysentery, measles and scarlet fever. In the *Semaine Médicale*, in 1900, Fournier reported a case of diabetes in a heredosyphilitic child of 8, who recovered after a course of antisyphilitic treatment. A family tendency is frequent; I have observed a number of cases in adults in the same family.

Isenflamm saw 7 diabetic children in one family: Thomas, 3; Naunyn, 5; Caron, 3 (3 months, 1½ years and 3½ years). I have seen 2 boys, 3 and 5 years old, respectively, who had a daily output of from 2 to 4 per cent. of glucose. They are at present 11 years older, have been seen by many physicians in America and Europe, have never been without an equal degree of glycosuria and have always been and still are remarkable specimens of physical development and robust health. The specific gravity of diabetic urine in children whom I have observed has varied from 1.005 to 1.044. The first instance of urine with a specific gravity of 1.0007, I found in a nervous girl of 17. The highest percentage of sugar in any case was 6.5; Hugnier reports 8.5 per cent. in a child who voided *5,000 c.c. (1¼ gallons) daily*, and Leroux reports 10.5 per cent.

In the treatment of diabetes it should be remembered that "gluten flours" are mostly unmitigated swindles. I never examined any without finding large amounts of starch. Of 13 specimens examined by the New York Health Department, only 2 were found to be "comparatively free from starch." The good results von Noorden has attained with his oatmeal diet show that carbohydrates are not so dangerous as many believe, particularly is that so when their antifermentative effect is required to abate acidosis which so frequently follows a case of fat feeding. Animal fat (cream) is a frequent cause of the formation of indican and acetone bodies; vegetable oils are better tolerated; milk is generally well borne and is useful in large quantities when taken slowly. I have given antipyrin with some advantage, but have never administered it for a long time. Adults have taken a gram (15 gr.) of sodium salicylate three times a day after meals, always with as large a dose of sodium bicarbonate. Alkali should be given constantly in large doses. The taste of bicarbonate of sodium is not loathsome to everyone. I believe that I have seen good results from the use of arsenic; it seems of value in adults. I begin with moderate doses, amply diluted after meals, and increase the dose slowly but persistently. In this way 10 minims a day may gradually be increased until 50 or 60 minims are taken without toxic symptoms. Opium is a remedy which surely diminishes the quantity of urine and of glucose. *Its detrimental effects are so well known and still more feared—quite often unnecessarily—that it is important to insist on its possibilities for good.* I feel sure that there are very few patients with diabetes that can not be benefited by opiates during some part of the treatment. It may often be combined with atropin or belladonna.

Having seen Dr. Rudisch's patients, I am impressed with his results. That is why I have followed his advice in a fair number of cases during the past half year or more. In so doing I have an advantage on account of the knowledge obtained during the past fifty years, that in order to attain the effect of atropin it must be given in active doses.

The first symptom of a full, that is, active, dose, is the flushing of the child's cheeks, making it look "feverish" half an hour after each dose, continuing for a period of half an hour or more—not a dilated pupil and no particular dryness of the throat. If a child of 2 years flushes up after 6 or 8 or 10 drops of the tincture of belladonna, let that be the dose. As soon as the effect is no longer needed, increase the dose, drop by drop. In administering atropin to adults, one must, in most cases, get the dry throat and rather blurred vision; to modify the effect an opiate may be added. I have never used atropin in a case of diabetes in a child for a long time.

DR. C. G. KERLEY, New York: The two boys have not had less than 6 per cent. of sugar in the last eight years. Including those two, I have seen eight undoubted cases of diabetes in children. The other six cases were rapidly fatal. One patient was *nineteen months old* and died within three months. The boys, 11 and 15 years of age, are clinically perfectly well. Diabetes in children is associated with much thirst and the passage of large quantities of urine. These boys have good appetites and sleep well. There is no excess in the passage of urine and no excessive thirst. They have been a puzzle to two continents. The older boy, six feet in height, and weighing 170 pounds, took three gold medals and three silver medals this year for long jump, high jump and other athletic feats. The younger brother is of exactly the same type. They excrete sugar on a very strict diabetic diet, and though the excretion of sugar continues, they continue to thrive and grow. They are living on a proteid diet and what the outcome will be we do not know. They are not ill, do not feel badly, and never have. The fact that sugar was found occurred through the desire of the mother to know that her four children were all well, as mothers will. She sent me a specimen of the urine of all four and I found the sugar in the two cases. The sugar was only discovered because the mother wanted the urine examined on general principles.

DR. JULIUS RUDISCH, New York: Dr. Jacobi means that to get the effect of atropin one must push the remedy until the physiologic effect is obtained. To a child I have given as much as 1/10 grain of atropin in one day and to an adult as much as 1/6 grain in a day without any bad results.

ACANTHOSIS NIGRICANS

A SYMPTOM OF A DISORDER OF THE ABDOMINAL SYMPATHETIC [*]

S. POLLITZER, M.D.

NEW YORK

HISTORICAL SKETCH

In 1889 a woman who presented a group of symptoms hitherto undescribed entered Dr. P. G. Unna's clinic for skin diseases in Hamburg. The case was referred to me for description and publication, and the report appeared in the *International Atlas for Rare Skin Diseases* in 1891 under the title of "Acanthosis Nigricans." Before the publication of my paper a similar case was observed by Janovsky of Prague, who sent the description of his case to the *International Atlas,* and the two cases appeared in the same issue, Janovsky accepting for the disease the name which had been proposed by Unna.

On the occasion of my visit to Paris in the summer of 1890, Darier showed me two cases of the same disease which had shortly before come under observation at the Hospital St. Louis, and which he published in 1893 under the descriptive title of "Dystrophie papillaire et pigmentaire." Since that time about fifty cases of the disease have been recorded in various parts of the world, and the condition is now recognized everywhere as a distinct clinical type. But an acquaintance with the condition, which is certainly more frequent than published reports would indicate, has evidently not been brought home to the profession in general, and it is the purpose of this paper to aid in diffusing knowledge of a disease which is of the gravest import to the patient.

DESCRIPTION

The cutaneous manifestation of the disease may be summed up as a widespread pigmentation and papillary hypertrophy. These two disturbances are in the main associated, affecting the same regions, though occasionally there is pigmentation without noticeable papillary hypertrophy, and on the mucous membranes there is the papillary hypertrophy without pigmentation. The regions of the skin affected are, in their order of frequency in the cases recorded, the axillæ, the neck, the external genitals, the groin, the face, the inner aspect of the thighs, the flexor surfaces of the elbows and knees, the umbilical region, the perianal region, the back of the hands, the breasts, the gluteal region, the hypogastrium, the forearms, the perineum, the eyelids, etc., and there is usually the most perfect symmetry in this distribution. For the recognition of the disease the symmetry and typical localization are scarcely less important than the occurrence of the cardinal symptoms of hyperpigmentation and papillary hypertrophy, while of secondary importance is the absence of certain other conditions, namely, scaling, hyperkeratosis, xerosis and itching.

---

[*] Read in the Section on Dermatology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

The first published case of this disease serves so well as the type of the cases subsequently recorded that I can best convey an idea of the clinical picture of the disease by repeating the description given at that time.

REPORT OF TYPICAL CASE

Patient.—Mrs. L., aged 62, widow. No history of tuberculosis or of syphilis. Patient had always enjoyed excellent health. Her skin disease had existed for about eight weeks, and had attacked all the affected regions at about the same time. There was at first everywhere, except on the hands, a slight prickling sensation which ceased in the course of a few days.

Present Illness.—The disease affected the upper extremities, the neck, the mouth, part of the trunk, and the genitocrural regions. The skin of the hands was in general of a dirty brownish color; on the back of the hands there were patches of a bluish-gray, somewhat deeper in color along the course of the veins. The normal areas of the cuticle were very prominent, standing out somewhat convex and with a glassy shimmer; some of them showed several glittering points corresponding to the smaller subdivisions of the cuticular areas. The natural furrows were deeply marked, the skin of the entire hands looking as if it were too large for them. On the back of the proximal phalanx of the thumb there was a patch the size of a shilling in which the dirty discoloration and the prominence of the cuticular areas were especially marked, giving the patch the appearance of a diffuse flat wart. The skin of the entire hand was rough and inelastic. The palms were slightly darker than normal; their furrows and folds were strongly marked and the skin felt dry, hard and thickened. On the anterior surface of the lower third of the forearm the peculiar discoloration was very striking and numerous small brownish patches, like freckles, were to be seen. On the dorsal surface of the forearms the discoloration was especiallly marked over and along the course of a vein. On the upper arms there were several lentil-sized warts which were said to be of recent development. The neck appeared as if encircled by a dirty dark grayish band which sent irregular offshoots downward toward the sternum, clavicles, shoulders and scapulæ, and upward toward the face. The skin here showed the changes described as existing on the hands, but in a much more marked degree. Some of the cuticular areas projected above the general level almost like papillæ, others were flatter; the whole running together to form a diffuse, discolored, warty surface. Similar changes were seen in both axillæ and under both breasts, only that here the coloration was rather grayish-white. On the abdomen there were a few horizontal linear indications of a similar condition. The crurogenital folds and the large labia showed the same changes in a marked degree. The entire region presented a grayish discoloration and diffuse warty prominences, the latter especially marked in a grayish-white patch, about 3 cm. in diameter, to the right of the vulva. There was a slight indication of the disease on the chin and on both auricles. From the beginning the tongue and mouth were painful. The anterior half of the hard palate was covered with fine granulations resembling small venereal warts but softer to the touch than these growths. A few outlying patches of a similar growth were seen on the posterior half of the palate. The upper surface of the tongue, especially in the middle line, was covered with more or less prominent condylomatoid growths, the morbid process sparing only a narrow strip on each side extending from behind forward to a point above 2 cm. from the tip. These lateral strips were free from prominences, smooth, and of a bluish-white color, and at their borders, as they merged into the affected region, there were numerous small discrete papillary growths. Underneath the plate of artificial teeth the depressions for the teeth on the lower jaw were seen to be occupied by similar warty growths. A like condition was seen on the mucous membrane of the upper lip and extended for about 2 cm. beyond the commissures of the lips, as an irregular prominent grayish mass resembling a large venereal wart.

Course of Disease.—After four weeks of energetic local treatment the condition remained practically unchanged and the patient left the clinic. Three or four months later a gradual improvement set in and the patient's skin and mucosa finally resumed a nearly normal appearance. By this time, however, she was complaining of great general debility and there was a very marked edema of the ankles. The daily quantity of urine was under the normal, but there were at no time albumin or renal elements in the urine. Meteorism and a slight abdominal ascites were noted. The general asthenia and the oliguria grew more marked till complete anuria set in, the patient dying from heart-failure, without symptoms of uremia, ten months after the onset of the cutaneous disorder. The clinical diagnosis of abdominal carcinoma occultum was made. A postmortem examination was not permitted.

ASSOCIATION WITH CANCER

When, in 1893, Darier published his two cases, in each of which there was an abdominal cancer, one with unmistakable clinical symptoms of that disease, the other showing extensive carcinoma of the abdominal organs on autopsy, the thought lay near that the peculiar cutaneous disturbance was etiologically associated with the abdominal cancer. This suspicion was strengthened by a series of cases which soon followed, in all of which there was either a demonstrable carcinoma of an abdominal or pelvic organ or strong clinical grounds for suspecting a malignant growth in this region.

BENIGN OR JUVENILE FORM

Then came several observations of a similar cutaneous condition—pigmentary and papillary hypertrophy—in children or adolescents who seemed in excellent health and in some of whom the cutaneous disorder had existed without change for many years. These juvenile cases obviously required a modification of the view that acanthosis nigricans was dependent on the presence of a malignant growth. As the observations of juvenile and adult cases multiplied some differences were noted in the cutaneous manifestations of the two classes of cases as well as in their course. In the juvenile cases the skin dystrophies are rarely so well marked or so extensive as in the adult cases. In them the disease, once established, usually remains stationary for an indefinite period—in one case over forty years—while in the adult cases the cutaneous lesions undergo fluctuations in their development, sometimes even disappearing completely. In the juvenile cases the health of the patient seems little, if at all, disturbed, while in the adult cases the patients rarely survive more than two years after the appearance of the skin lesions, their average duration of life being a little over one year.

UNPUBLISHED CASES

Cases of acanthosis nigricans have been reported from almost every country of Europe—France, Germany, Austria, Russia, England, Switzerland, Norway, Finland, Bulgaria and Turkey; but from the United States only one case has been published, that of Dr. Roblee of Los Angeles, a case which belongs to the juvenile type. Through the kindness of Dr. Grover Wende of Buffalo I am able to add two unpublished cases to this list, one occurring in a woman, aged 42, of American birth, suffering from cancer of the uterus with abdominal metastasis. The papillary and pigmentary dystrophy affected the neck, axillæ, umbilicus, groin, anogenital region and elbow. In the mouth there were large papillary excrescences; under the breasts there was pigmentation without papillary hypertrophy. The patient died about two and a half years after the onset of the cutaneous disorder. I saw photographs of this case, which was typical. Dr. Wende's second case occurred in a boy of Italian parentage, 8 years old, the disease having appeared one year before. The skin lesions, says Dr. Wende, were well marked and occupied the usual regions. The child had a greatly distended abdomen, was under observation about one year and during that time lost weight. The case was lost sight of and its further course is unknown. It is a question whether this case belongs in the juvenile group, as the patient's age would indicate, or whether there may not have been a malignant growth in the abdomen.

Dr. Ormsby of Chicago informs me that he has seen such a case in the practice of Drs. Hyde and Montgomery in a lad of 15 who was an extreme alcoholic, and I am indebted to these gentlemen for a copy of the late Dr. Montgomery's notes of the case. The patient was 16 years old, in good general health, and weighed 215 pounds (98 kilos). His skin disease began about a year before as a pigmentation in the axillæ, groins and around the neck. Its color ranged from a pale yellow-brown to almost black and was most marked about the nipples, umbilicus, axillæ, inner sides of the buttocks, anus, genitocrural region, over abdomen and neck, and was present in lesser degree over the abdomen, chest, middle of the back, angles of the mouth and the sides of the nose and the eyes. A papillary hypertrophy accompanied the pigmentation, and in general was more marked the deeper the pigmentation, ranging from soft velvety prominences to large wart-like and filiform growths. The mucous membranes of the lips and cheeks (and tongue?) showed beginning thickening and had a grayish color. The case was seen but once, and nothing is known of its further course. It is worthy of remark that alcoholism has been noted in a fair number of these cases.

I have no doubt but that many cases besides these have occurred in this country. I was recently called by Dr. Morris Manges of New York to see a woman, aged 42, *in articulo mortis* from cancer of the colon (a large tumor being palpable in the right hypochondrium) who presented a broad band of pigmentation encircling the neck, and at the back of the neck an area extending from the border of the hair to the sixth cervical vertebra and laterally to the anterior border of the sternomastoid muscle on each side, which presented the typical appearance of acanthosis nigricans, being covered with a uniform, slaty-brown, velvety mass of hypertrophied papillæ of an average height of 3 or 4 mm. On the back of the third and fourth finger of each hand there was a flat, pigmented, warty growth about 6 mm. in diameter; and there were similar but smaller pigmented, flat, warty prominences on the upper surface of all of the toes at their junction with the foot. The mucosæ were normal. The pigmentary and papillary hypertrophy at the back of the neck had been seen by Dr. Manges two and a half years before, but the area involved was then smaller. I have no hesitation in including this case in the group of acanthosis nigricans, though the case is atypical in the slight extent of development of the lesions and their absence from the mucosæ. It may be called an *acanthosis nigricans partialis.*

MULTIPLE PIGMENTED WARTS IN CANCER OF THE COLON

The question arises whether an atypical mild case like this may not be regarded as a connecting link between the fully developed acanthosis nigricans and the condition of multiple small pigmented warts, pigmentary patches and telangiectasis occurring on the abdomen of patients affected with abdominal cancer, to which Holländer[1] has directed attention and to which he ascribes a diagnostic value in the early recognition of cancer of the colon. His observation has been corroborated by numerous writers, and Dr. Willy Meyer of New York, in a communication before the American Surgical Association, 1906, narrates several cases of this kind and does not hesitate to call this condition acanthosis nigricans. He has seen the little warty growths and the pigmentations disappear after successful operation for the colon cancer which provoked their development. For my part I should hardly feel justified in including these insignificant pigmentary deposits and warty growths, limited to the abdominal parietes, in the same group as the severe and extensive lesions of acanthosis nigricans. Certainly the multiple angiomas described have nothing to do with acanthosis. It is nevertheless undeniable that these lesions, representing a papillary and pigmentary dystrophy, however limited, occur in many cases of cancer of the colon and at least the possibility of a related pathogenicity must be admitted.

Including Wende's two cases, the Hyde-Montgomery case and my second partial case, there are a total of fifty-two cases of this disease thus far reported. Twelve of the patients are reported as having died, all of them of carcinoma, with the possible exception of one patient, Burmeister's, to whose case I shall presently refer. It must be remembered that most of these cases are reported at the time they are seen, and their termination is left unrecorded. We can judge of their probable course only from their clinical symptoms. In a recent publication Bogrow,[2] in a tabular list of 49 recorded cases, enters the case of every patient over 20 years of age, with the exception of Brocq's case, which I shall presently consider, as malignant or probably malignant, using this term as implying such grave symptoms as would suggest a fatal termination. "Brocq's case" is an example of the persistence of error. Brocq refers, in the course of a discussion on this subject, to a case of pigmentation in the axillæ and groin with a suspicion of papillary hypertrophy occurring in a healthy woman of 38 in whom all the cutaneous lesions vanished spontaneously in the course of a year. He says distinctly[3] that this is not a case of acanthosis nigricans—"il ne s'agissait pas réellement d'acanthosis nigricans"—but nevertheless "Brocq's case" is constantly referred to. It should be thrown out!

The accompanying table of known cases is taken with modifications and additions from Bogrow's table:

TABLE OF KNOWN CASES OF ACANTHOSIS NIGRICANS

Age.	Author.	Course.
2.	Barsky-Pospelow	Benign.
2.	Buri	Benign atypical.
3.	Wolf-Hügel	Benign.
3.	Spietschka, Case 2	Benign.
5.	Filser	Benign.
8.	Wende, Case 2	Benign?
9.	Frankenstein-Juliusberg	Benign.
11.	Jacquet-Delotte	Benign.
12.	Roblee-Boggs	Benign.
14.	Neumann (Rille, Case 2)	Benign.
15.	Spietschka, Case 1	Benign?
15.	Hyde-Montgomery	Benign?
18.	Mzareulow	Benign atypical.
18.	Françon	Benign atypical.
18.	Rille, Case 2	Benign?
18.	Rille, Case 3	Benign?
19.	Pawlow	Benign atypical.
19.	Spietschka, Case 3	Malignant.
28.	Hodara	Malignant.
29.	Darier, Case 3	Malignant.
33.	Darier, Case 1	Malignant.
34.	Morris	Malignant.
34.	Grouven-Fischer	Malignant?
35.	Burmeister	Malignant.
35.	Becker	Malignant?

RELATION TO ABDOMINAL CANCER

Deducting 17 cases of patients under 20 years of age from the 52 known cases, we have 35 cases of patients over 20 years of age, in 22 of whom, or over 60 per cent., there was certainly or most probably a carcinoma present. In 14 of these cases the carcinoma affected the alimentary tract, in 5 the uterus, and in 3 the breasts; in two of these last there were abdominal metastases. In this list of malignant cases one of Spietschka's is included, though the patient was but 19 years old. This occurred in a young woman who presented a typical and severe case of acanthosis nigricans developing after an abortion and was found to have a chorioepithelioma of the uterus. A radical operation resulted in a cure and four and a half months after the operation all signs of acanthosis nigricans had disappeared. This case may be explained on the assumption that there were small metastatic deposits of the chorioepithelioma in the abdominal cavity provoking a disturbance in the functions of the adrenal sympathetic system, which underwent involution after the removal of the primary tumor. On this point Wells says:[4] "It occasionally happens that after removal of the primary tumor the secondary growths seem to lose their power of proliferation so that they become entirely replaced by fibrous tissue."

To the twenty-two positively or almost certainly malignant cases six more may be added in which the presence of abdominal cancer was on clinical grounds in high degree probable. Altogether we have, therefore, twenty-eight cases (80 per cent.) most probably carcinomatous out of thirty-five adult cases—so large a proportion that the relation of acanthosis nigricans to abdominal cancer must be regarded as established beyond question.

I have referred to Burmeister's case, which is usually quoted as a typical case of acanthosis nigricans in which a postmortem examination showed no tumor of the abdominal organs. In this case the gastric crises, the alternations of anorexia and bulimia, the cardiac attacks, the progressive asthemia, and the death from heart-failure make an unmistakable picture of disease of the adrenal system. The autopsy was made after decomposition had advanced so far that a proper postmortem examination was impossible and the only positive finding was degeneration of the heart muscle, a common occurrence in Addison's disease. For any light it threw on the case, the autopsy may as well have been omitted.

Summing up these adult cases, we may say that in an overwhelming preponderance of the cases there is positive or most probable evidence of malignant disease affecting the organs of the abdominal cavity, and on physiologic grounds we may assume an interference with the functions of the abdominal sympathetic as the immediate link in the causation of the cutaneous manifestations. This is the mechanico-nervous theory proposed by Darier to which I subscribe.

How is it with the juvenile cases? In them there is evidently no progressive growth and we can only speculate that there is a congenital abnormality such as fibrous bands or a benign tumor interfering up to a certain point with the sympathetic functions. One case in which there was a deformity of the thorax and one in which the acanthosis nigricans developed after a blow in the epigastrium lend some color to these speculations. What is still needed to establish the relation between this remarkable dermatosis and a lesion of the adrenal sympathetic system is a thorough postmortem examination.

Note.—For the literature of acanthosis nigricans the reader is referred to Janovsky (Hyperkeratoses, in Mracek's Handb., iii, 97), and to Grouven and Fischer (Arch. f. Dermat. u. Syph., lxx, 237). The more recent cases may be found in Bogrow (Arch. f. Dermat. u. Syph., xciv, 297). To these I must add Pribram's case (Deutsch. Arch. f. klin. med., 1909, p. 407).

51 West Sixtieth Street.

ABSTRACT OF DISCUSSION

Dr. William A. Pusey, Chicago: I can add one case to Dr. Pollitzer's group. Three years ago I demonstrated a case before the Chicago Dermatological Club which, I believe, was accepted as one of acanthosis nigricans without dissent, and of which I subsequently showed illustrations in this Section. It was not a case of the extreme type. The lesions were developed in the mouth and around the neck, in the axillæ and groins, about the navel and perineum, and about the external surface of the elbows. The pigmentary spots were more marked than the papillary hypertrophy. The patient was kept under observation for about two years, and during that time there were no evidences of carcinoma in any part of the body, and I think it is reasonable to suppose that other than carcinomatous forms of irritation of the abdominal sympathetic might be the causative factor. In my case the patient was a man between 60 and 70 years of age, who was obtunded somewhat mentally.

Dr. A. S. Wolf, St. Louis: I would like to mention a case of acanthosis nigricans occurring in my practice several years ago. The patient was a woman of 35, who came to me for treatment of universal inveterate psoriasis vulgaris. Besides the patient presented universal adiposis (weight 205 pounds). The hypertrophy was marked in the collar line of the neck, mostly in the rear, gradually decreasing toward the front. The lines of the skin became deep furrows and the whole had an appearance of lichenification. The skin in both axillæ presented the same appearance, especially on the upper edge of the arm-pits. The skin was of a dirty blackish appearance, in some places darker, in others the pigmentation was less outspoken. Under the finger the involved skin appeared thickened without being indurated. The mucous membrane and the other parts of the skin were free. The patient could not make any statement as to the duration of the process, neither did she allow the excision of a skin specimen. There was no family history with the exception of a case of psoriasis in a sister, who also presents conspicuous adiposity.

Dr. O. H. Foerster, Milwaukee: I have seen five cases of acanthosis nigricans, one of which has already been referred to by Dr. Pusey; the others I saw in clinics abroad. The point that struck me particularly was the etiology, for in all of these cases the patients had been exposed to extreme degrees of heat, two of them being workers in a brick-kiln. Dr. Pusey's patient had been a stoker on a steamer.

Dr. S. Pollitzer, New York: Of course, it is hard to judge of the value of these cases from partial communications. We all know how hard it is to make a clear mental picture of a cutaneous disease from a mere description of it. I have again and again been asked to see cases of supposed acanthosis nigricans, but with the exception of the one reported in my paper, they were all cases of various atypical pigmentations, such as arsenical pigmentation or ichthyosis. One should be a little careful in making the diagnosis of acanthosis nigricans, unless the lesions are typical. In Dr. Pusey's case of pigmentation with papillary hypertrophy, there was pigmentation of the visible mucous membranes, and there were lesions on the posterior surfaces of the extremities; such changes have not been observed in any of the cases reported. Of course, it must be borne in mind that these are atypical of acanthosis nigricans.

---

[4] Wells, H. G.: Resistance of the Human Body to Cancer, May 29, 1909 lii, 1737.

In regard to the case associated with psoriasis, which was mentioned by Dr. Wolf, we must remember that there may be pigmentation in psoriasis, especially if arsenic has been used. As to the five cases seen by Dr. Foerster, that is certainly an extraordinary number. That the disease has occurred in persons who have been exposed to great heat is an observation that has been made before in a few of the cases, and can not be regarded other than as a mere coincidence. We must not forget that exposure to great heat is apt to bring about, through hyperemia, pigmentation of exposed parts; but it would require more than that to constitute a case of acanthosis nigricans.

SIMULATED INSANITY[*]

CHARLES K. MILLS, M.D.
Professor of Neurology in the University of Pennsylvania; Neurologist to the Philadelphia General Hospital
PHILADELPHIA

INTRODUCTION

One simulates insanity who, being sane, by his action and speech or by his suppression of both speech and action, tries to prove that he is of unsound mind. One who is insane may also feign the symptoms of a type of insanity from which he does not suffer. For one simply to assert that he is insane, which is occasionally done, does not constitute simulation of insanity. Such assertion must be accompanied by some evidences of the playing of the part in order to constitute feigning. One dissimulates insanity who endeavors to conceal the fact that he is insane. This pretense of sanity by the insane is a far more common procedure than the feigning of insanity by the sane.

Well-known historical instances of the feigning of insanity are to be found in the classical works on mental and forensic medicine—the feigning of Brutus in the time of the Tarquins, of Ulysses as recorded by Homer, of Solon in an effort to stimulate the Athenians to recover Salamis, and of David in the Old Testament. In each of these cases, and in other similar historical examples of simulation, the methods used to carry out the feigning were of a primitive, or at least of a comparatively simple character. They were, however, the methods which in some cases are still resorted to by the simulator, and this because the popular idea regarding insanity is not much in advance of the views held in the time of the Tarquins. They are methods based either on crude conceptions of the nature of mental disorder, or on the signs of such disorder as observed in two or three types of insanity. Solon's simulation of insanity was, as Dr. Lloyd[1] aptly remarks, an instance of the lawyer and not the client practicing simulation. It may be said, however, that, while the attorney does not himself feign insanity for a purpose, he has been accused, apparently with justice in some instances, of instigating such simulation in the client. Instances of such instigation are, however, extremely rare.

COMPARATIVE RARITY OF THE SIMULATION OF INSANITY BY THE SANE

Contrary to what is believed by members of the legal profession and the public at large, feigning of insanity is rare, and, above all, is rare in cases which come under observation in the private practice of medicine and in institutions for the insane. It is also comparatively rare, contrary to general belief, in cases in which the plea of insanity is entered as a defense in homicide and other cases. The most frequent instances of real simulation are observed in the military and naval service, in prisons, and in asylums or hospitals for criminal lunatics; but even in these it is not as common as is supposed. I have had no experience in the study of insanity, or of its simulation in criminal lunatic asylums, or in either the military or the naval service. My studies in penal institutions have been confined to the opportunities offered by one or two general investigations of the mental status of inmates of prisons, and to the examination of a considerable number of cases held for homicide or other serious offenses. The occurrence in prisons of insanity which is overlooked or disregarded is far more common than the simulation of insanity by prisoners.

In a recent homicide trial in which the plea of insanity was entered one of the medical witnesses for the prosecution, in response to a question by the attorney for the defense, said that he had seen about fifty cases of the simulation of insanity, mostly in the psychopathic wards of one of the hospitals in a large American city. In connection with the Philadelphia General Hospital are such psychopathic or detention wards, with which I have been connected for nearly a score of years, but, strange to say, I have never seen a single case of the feigning of insanity in those wards. Several of my colleagues, with whom I have conferred, have had the same experience.

In a large private and hospital practice extending over many years I can recall only a single case in which I was convinced that genuine simulation had been attempted, this not including the homicide cases to which reference will later be made.

It may happen, of course, that in particular periods a larger number of cases of simulated insanity occur in certain institutions, a fact which accounts in measure for the difference of opinion as to the frequency of simulation in prisoners and insane hospital patients.

OBJECTS FOR WHICH INSANITY IS FEIGNED

The objects for which insanity is feigned are various, among the most important being the desire to escape military service, to exchange less for more comfortable prison quarters, to annul contracts, and to escape punishment for minor or major criminal offenses.

In recent times a number of instances have occurred of the more or less successful feigning of insanity by newspaper reporters who have sought in this way to enter and sojourn in hospitals for the insane, in order to write sensational articles about the alleged abuses in such hospitals.

[1] Lloyd, James Hendrie: Insanity, Its Various Forms and Its Medicolegal Aspects, Book II; Wharton and Stillé's Medical Jurisprudence, Vol. 1, Edition 5, 1905

In 1889 a reporter succeeded by simulation in having himself committed to the Philadelphia Hospital for the Insane, where he remained for a few days and then published a story of what he alleged he had seen and heard which produced a transient sensation. He was probably never thoroughly examined by members of the hospital staff, although he was seen by several of them during his brief stay. Some points in the case are worthy of recall, as illustrating the manner in which the intelligent but badly informed simulator overdoes the rôle. No really insane man ever indulged in the entertaining and extravagant performances of this scribe. He was picked up while creating some excitement at one of the Philadelphia street corners. He asserted that he had lived at the bottom of the sea and was 1,000,000 years old, that he had had nothing to eat for ninety years, that he was the last of the actors, that they were all killed by the song-and-dance men—killed with cannon—and the leaves of the trees had turned red with their blood.

"My home," he said, "is in a cave in a mountain on the planet Mars. It was an elephant's nest, but I made friends with him and he brings me food every day. At night I sleep under the sea in a coral grotto, while mermaids sing me soft lullabies that woo the drowsy god." He kept up this farrago or something like it for a day or two; then his identity was disclosed and he was discharged from the hospital.

THE TESTING OF SIMULATION

It is not my purpose in the present article to go at length into the question of the methods of testing simulated insanity. These are given at more or less length in works on insanity and forensic medicine. They include many devices, such as making remarks regarding the patient or his symptoms which are calculated to induce the simulator to assume that which is suggested; suddenly charging feigning and watching the effects; the use of emetics, ether, chloroform, etc. It must be said that all such methods will fail in particular instances, either through foreknowledge of what is likely to be expected or through the natural shrewdness of the individual being investigated. Setting a watch by day and night through an opening in the wall, ceiling, or door is sometimes resorted to, and has occasionally proved efficient in unmasking a feigner. It fails sometimes, one of the reasons being that occasionally unusual powers of endurance and unusual cleverness in keeping up violent and grotesque speech and action are shown by the malingerer. Tests which involve the idea of anesthesia, which the simulator is likely to believe should be present, like the others, may fail, as may also those which involve cruel procedures such as the use of sharp or heated instruments, cold shower-baths, and physical punishment.

After all, the best procedures are those which are founded on scientific principles and the use of the ordinary methods of determining the presence of disease, mental and physical, including the study of the life history of the patient, a comparison of his present with his past behavior, the investigation of the manner in which the supposed insanity has appeared, and the determination of the existence of a type of insanity with more or less elaborate but correlated phenomena. Few simulators, for instance, have the ability to combine in one picture the symptoms of a form of insanity which contains in its ensemble phenomena of exaltation, depression, and suspicion, with certain details well known to be present. The feigning of mania, complete dementia, or stupor is perhaps most frequently attempted, but simulation is often charged in cases of paranoia. Mania or dementia are usually overdone by the simulator, as in the case of the reporter to which reference has been made. The character of the crime which has been committed and the manner of its commission may mean much to a thoroughly informed alienist.

One of the most difficult of problems connected with the question of simulation is that presented by cases of alleged or real insanity, usually forms of paranoia, or alcoholism, which present or appear to present only one or two delusions, such as those of marital infidelity and of poisoning, and yet such cases are among the most important in forensic medicine. In such cases the authentic history of the patient over a considerable period is of special value.

Mistakes are sometimes made by physicians, as well as by laymen, through not properly interpreting phenomena which appear to point to feigning. One of these not often dwelt on is that of supposing that acting, more or less consummate, is a proof of sanity. The putting of "an antic disposition on" is by no means always a proof of feigning. In katatonia, histrionism or theatrical behavior is frequently present. The poses, forced gait and declamatory gestures exhibited by a Chinaman recently tried in Philadelphia apparently did much to prejudice those who examined him, as well as the jury to whom his behavior was described, against the opinion that he was insane, and yet this conduct was one of the real evidences of his mental disorder.

THE DISSIMULATION OF INSANITY BY THE INSANE

The simulation—or, it would perhaps be better to say, the dissimulation or concealment—of insanity by the insane is comparatively frequent. The attempts at concealment are made for a variety of reasons—to escape from institutions by deceiving officials or visitors; to obtain discharge on a writ of habeas corpus; to arouse sympathy; to prevent certification, or the appointment of a committee; or to obtain certificates of sanity to be used as instruments of defense or aggression. Many such cases have come under my observation. In some instances the concealment of insanity has been so successfully practiced as to deceive not only laymen and legal advisers, but honest and capable physicians.

The insane who try to conceal their mental disorder sometimes have advantages over those who, being of a sound mind, simulate insanity. When the former have been inmates of hospitals for the insane, and are intelligent and observant, they have the opportunity not only of studying the phenomena of alienation as exhibited by others, but of learning through the examinations made by physicians what symptoms and signs are regarded as most significant of the presence of insanity. If they have sufficient mental power, profiting by the knowledge thus obtained, they are able (usually only for a time) to conceal the evidence of insanity in their own persons. When not inmates of institutions, they may in some cases, by simply closing their mouths and controlling their conduct, be able to keep in check or out of sight insane manifestations. It requires in some cases unusual skill and patience to elicit the evidence of insanity, and it may indeed be impossible to do this at some particular examination. Perseverance, however, will usually be rewarded by success.

Every neurologist or alienist of considerable practice is now and then asked to give a certificate of sanity, a request which in itself should incline him to be on his guard. In a few instances I have known unwary, although honest, physicians to give such certificates, which they subsequently have had cause to regret.

A woman who made the lives of some of her townsmen, medical and otherwise, and of at least one man of eminence in public life, more or less intolerable by her accusations and undesired attentions came to me from a distant state, as she had gone to others in more states than one, to obtain a certificate that she was sane. She was extremely persistent in her efforts. She was a woman of good presence and some ability, or at least she had superficial acquirements which she used to advantage in the pursuit of her purpose. It was only by a close study of the history of her case and of her statements and personal bearing that a conclusion was reached after several interviews. She undoubtedly belonged to that numerous class included under the broad term of paranoiacs, with delusions both of self-importance and of persecution, the former at the time of my examinations predominating. Her egotism amounted to a megalomania, and close investigation showed that she might become dangerous under provocation or indifference. My refusal, after careful study, to give the certificate desired freed me from her personal visits, but not from her abusive attentions by mail.

In another case—that of a man who had made his escape from an asylum in a neighboring state and was for a time in self-imposed seclusion—refusal after prolonged investigation to come over to the side of the accused again brought on me maledictions. This man had several interesting forensic campaigns in which the question of his sanity or insanity was the chief object of conflict.

A woman 35 or 40 years of age came to my office, accompanied by an intelligent young man who had espoused the cause of her sanity, as appeared later, and requested me to give her a most searching examination and tell her if I could find in her any signs of insanity. She was agreeable in her demeanor and apparently honest in her desire to arrive at the truth. Beginning with her earliest history, so far as could be learned from her statements, and continuing by methods of examination and cross-examination, I tried to penetrate the armor of deception with which she had encompassed herself. It was a long task and not an easy one, but after nearly two hours I determined to my own satisfaction at least that she was not of sound mind, and then learned that she had but recently been allowed to leave a hospital for the insane in which she had been confined for many months. In spite of her skilful resistance a delusional state was uncovered—one which had brought on herself and others much and somewhat serious trouble. Her concealment of her insanity was a more skilful piece of sustained acting than has ever come under my observation in any case of alleged simulation of insanity.

Another case, one of the most positive examples of dangerous paranoia which has come under my observation, was certified by another physician and myself to a hospital for the insane. He had hallucinations of hearing and of sight, delusions of persecution by unseen agencies such as electricity conveyed by wires, and other of the classical phenomena of this form of insanity. He had also well-marked delusions of self-importance, and had had episodes of excitement in which he threatened to kill his wife and others. After his admission to the hospitals he resisted all efforts on the part of the asylum physicians to demonstrate his delusional state. A writ of habeas corpus was asked for, and several eminent alienists and neurologists examined him with negative results. They could not obtain evidence which satisfied them that he was laboring under the delusions and hallucinations which had led my colleague and myself to certify him. The case was heard before one of the most conservative of our Philadelphia judges, and on the testimony produced at the hearing the man was remanded to the hospital for further observation. He still successfully continued his policy of suppression, and was some weeks later brought into court and this time discharged. His later history was interesting and somewhat dramatic. His delusions after he was set at liberty again became apparent. He made many threats and several assaults, and after some difficulty he was again certified and sent to one of the state hospitals, where he still was a short time since, his insanity being almost continuously in evidence. It was only by the most fortunate chance that this man did not kill some of those who were the objects of his insane suspicions.

Paranoia is not the only form of insanity which is occasionally successfully suppressed or abates in such a way as to deceive those usually capable of determining its presence.

A few years since, on the certificate of another physician of Philadelphia and myself, a paretic patient was sent to one of our best known hospitals for the insane. Partly by personal suppression and partly, no doubt, under the influence of conditions which bring about marked remission in symptoms, this man became so quiet and self-controlled as to deceive a physician of some distinction, and also apparently some of the physicians of the hospital, into the belief that he was either not insane or had recovered. He obtained his discharge from the hospital, and immediately went about securing the services of attorneys to bring suit against myself and others for conspiracy in having him placed in the institution. While some attorneys refused, he succeeded in obtaining the services of one or two, and had carried matters so far that suit was about to be entered when his insanity became so apparent, even to those who were helping in his crusade, that all concerned were placed in an unpleasant predicament. Eventually he was returned to the hospital.

SIMULATION IN HOMICIDE CASES IN WHICH THE PLEA OF INSANITY IS OFFERED

In order to recall some facts of value from experience I have collected the data of twenty-four cases in which in trials for homicide the plea of insanity was entered as a defense. In these cases I appeared seventeen times as a witness for the defense; three times as witness for the prosecution; as special adviser three times, and once as arbiter, chosen by agreement of defense, prosecution and the court. By adviser is meant that I was called on to counsel with the attorneys either for the defense or prosecution; for the former in two instances and the latter in one. Simulation was charged or inferred by the prosecution in twelve cases; in two cases the plea of insanity was accepted with little or no contest. It might be said in passing that in both of these instances the accused were women. Ten cases were tried on their general merits with little or no reference to the question of simulation; that is, it was simply held by the prosecution that the accused were not insane, and by the defense that they were.

Recalling these cases after many years, my judgment has but little changed from the time when, full of interest in the details of the investigation and in the events of the trial, I held to my conviction as to the sanity or insanity of those under trial or about to be placed on trial.

In only one case was I impressed with any considerable doubt as to the validity of the insanity plea, and in this case the man himself constantly asserted that he was not insane. It was indeed not held that he was, except at the time of the commission of the crime for which he stood accused, and which was not denied by him or his counsel.

The case was one in which the evidence seemed to point to transient insanity in an epileptic—a most difficult plea to uphold, and yet one than which there is none more likely to be just if the history of the case affords sufficient proof. The man had an attack of spasm apparently with unconsciousness in the court. I was not present at the time and had not the opportunity of studying his condition during the seizure, but a physician of ability, although one not an alienist or neurologist, believed that the attack was genuine. The accused had on his head the scar of an old injury, pressure on which caused pain and brought on a vertiginous state.

Of the seven cases in my list in which there was acquittal on the plea of insanity in only two was there any possibility of simulation, and in both of these cases this might be regarded as doubtful. One of the accused, however, was a highly educated man and had the ability and probably the knowledge of mental disorders necessary to aid him in his purpose if he designed to feign. The other was an ignorant but rather shrewd man, who might have made a rude attempt at simulation. In the first case the evidence as to the existence of melancholia was sufficiently decisive, and in the other acquittal was obtained from the standpoint that the man was suffering from a form of delusional and hallucinatory insanity with amnesia.

As has already been indicated, three of those acquitted were women, and sex probably had as much as anything else to do with the rendering of the verdicts. In two of these acquittal was practically ordered by the judge with the acquiescence of the prosecuting attorneys, and I have no doubt that in both instances the best interests of justice were furthered by the action. In the other case the woman was acquitted in spite of vigorous resistance on the part of the prosecutor. I was not retained as a witness in this trial, but was familiar with the details of the case, and was employed to give an opinion some time after the conclusion of the trial as to whether she should be released from a hospital for the insane to which she had been sent after her acquittal. The cases were fought out mainly on other lines than simulation.

Without doubt the feeling in the minds of judges, juries and the public is against the infliction of capital punishment on women, although at times this feeling is overridden in the interests of justice or for other reasons not always apparent.

In another case after a careful examination of the prisoner and a careful going over of the history of his case and the testimony, I came to the conclusion that the interests of the defense would be best served by not calling on experts, rather trusting to lay and ordinary medical evidence and to the eloquence of the attorneys. The man did not make the slightest attempt at simulation, at least not at the time of my examination. He seemed careless of results and not desirous of being regarded as insane.

In the seventh case the testimony was conflicting, but the accused was sent to an asylum as the result of an agreement to have the case arbitrated by some one who would have no connection with the trial or the investigations leading to it. Feigning, so far as I know, was not attempted.

Several years since with Dr. E. N. Brush, now superintendent of the Sheppard and Enoch Pratt Asylum, at Towson, Maryland, I was employed as a witness in the case of a German who had committed homicide. After this man's execution his brain was secured by Dr. Brush, who made a report, not only on the case in its general features, but on the findings of the necropsy. The brain was extensively diseased. The lateral aspect of the right hemicerebrum showed a marked porencephaly. There was arrested development in the left half of the body, the patient having been asymmetrical from birth. His skull was asymmetrical. He had the history of having a fall, was intemperate, and had had a sunstroke. His knee-jerks were absent, his pupils unequal, and his symptoms and the postmortem findings pointed to general paresis in addition to the congenital or infantile arrest. He was 57 years old at the time of the trial.[2]

It is a matter worthy of passing notice that one of the chief elements which appeared to bring about the conviction of this man was the use which the prosecuting attorney made of the excitement with which the country was then filled about anarchy and anarchists. The trial was held a short time after the Haymarket crime in Chicago, at which time a number of police were killed or wounded as the result of bombs alleged to have been thrown by anarchists, several of whom were afterward tried, convicted and executed for inciting the crime. The prisoner was a German, and this with the homicide itself was sufficient to make him an anarchist and anarchy responsible for his deed.

The only woman whom I remember to have been executed in Philadelphia during my professional life was a weak-minded and probably irresponsible creature, although not in a technical sense insane—not one whom physicians would have been likely to certify to an institution after the usual examinations. This woman had not sufficient mental power to feign with success anything that required the exercise of any considerable degree of intelligence. She poisoned several of her children by administering arsenic to them in their food, this crime seemingly having been done for the purpose of collecting a small insurance on their lives.

An early case in my experience was that of a man who had killed his mother-in-law and wounded his wife. He was supposed to be suffering, among other things, from delusions of marital infidelity. These, as every experienced alienist knows, are among the most dangerous of all delusions. They are sometimes associated with few other evidences of insanity; they occur in cases both of alcoholism and other drug habits and in constitutional paranoia. They are likely to be looked at askance by judges and by the community as represented by juries. One insane in this way is never likely to admit his insanity. Four men out of five appointed by the governor to inquire into the sanity of the accused reported him as insane, but the governor refused to pardon him and he was executed. That simulation was not practiced in this case was my judgment and that of my colleagues, although this may not have been held by others.

---

[2] Brush, E. N.: Polyclinic, Philadelphia, vol. 5, 1888.

On Oct. 17, 1887, was begun one of the most interesting trials for homicide in the annals of Philadelphia jurisprudence. Oscar Hugo Webber, on Dec. 6, 1886, without provocation, killed William Martin, a jeweler. Webber, about a week previous to the shooting, had taken a clock to Martin to be repaired. When the work was done he took the clock home, but about a week later brought it back. He and the jeweler had some words, when the former drew a pistol and fired four shots, killing the latter. Webber's father was insane, and one of his sisters was an epileptic. With Dr. James Hendrie Lloyd I examined him for the attorneys who had been appointed by the court to defend him, visiting him five times in all. I became thoroughly convinced of his insanity.

At the trial a considerable number of witnesses, both medical and lay, testified to his delusions and insane acts. One physician, who had known him for ten years and attended him and other members of his family, had some time before the homicide recommended that he be placed in a hospital. The accused believed that his wife was unfaithful to him, and wished to drug him to get him out of the way, and that his children were illegitimate. He also believed that he was the victim of persecution of his friends, relatives and fellow workmen, and even those with whom he came only occasionally in contact. No clearer case of insanity was ever admitted to a hospital for the insane.

No medical evidence was offered in rebuttal, although several lay witnesses testified in rebuttal their belief that he was sane. It is to be inferred that the prison and other physicians who are known to have examined him in prison before the trial, had reported to the district attorney their belief in his insanity. Whatever is the truth regarding this, it remains that they were called neither by the prosecution nor by the defense. Webber was convicted and sentenced to death. Evidently, however, some force was at work which withheld the hand of the law in the final act. He remained in prison until he died, becoming more and more delusional and demented.

Dr. Lloyd[3] has written an interesting article regarding this case.

In this case an effort was made to have proceedings instituted to determine, first, the extent of sanity or insanity of the accused, but it was decided that the trial should go on in the usual manner. As Lloyd remarks, although the law authorizing the procedure would appear to be one adapted to furthering the ends both of mercy and of justice, it is seldom invoked in the defense of those homicides alleged to be insane.

The case was relentlessly pressed to conviction. Simulation was not attempted by the accused. When the man rose to plead, instead of leaving this duty to his counsel, as is usually done, he stammered some incoherent words. When he was ordered to sit down, the judge exclaimed, "We will have no Guiteau business here." On one or two occasions when Webber was examined, efforts were made to get him to give some reason for the killing of Martin, who had not injured him in any way, but the accused said he would tell all about it when he got to court. He seemed to have some insane idea that he would exculpate himself by telling the court why he had done the deed. It is doubtful whether he had sufficient mental power to carry out even the feeblest effort at feigning, if such an idea had ever entered his mind.

A homicide of great interest and one in which simulation was charged was that of Joseph Taylor, who in October, 1884, was convicted of murder in the first degree, he having killed a prison keeper. Taylor was a man of low type, a so-called social Pariah, who had been arrested and convicted of numerous crimes. His brain was an interesting teratologic study, and was one of several criminal brains described by me in the presidential address[4] before the American Neurological Association in 1886. One hemisphere was distinctly different from the other in bulk and height, and the lobes, gyres and fissures presented many fetal and ape-like similarities. It was a low-type, arrested, aberrant human brain in the fullest meaning of these words.

The conclusions reached by the medical investigators and witnesses for the defense was that Taylor was a delusional monomaniac of the so-called criminal or prison type. He was, so we believed, the victim of well-marked delusions of persecution, these being more or less connected or correlated, and having reference to the putting of injurious or poisonous medicines into his food and drink, and to bad treatment from the warden, keepers, doctors and prison officials generally. Numerous other factors entered into the delusional state of the accused, but it is not in the scope of this paper to discuss this or any other case in much detail. The question of simulation was made an important one in the course of this trial. Testimony of the prison physicians was produced which showed that he had told the doctor several times before the trial that there was nothing in the crank business and that he was going to work. On the first day of the trial Taylor had several outbreaks in the court, which impressed some with the idea of feigning, and others that they were somewhat additional evidences of his insanity. Whether Taylor did or did not simulate in prison and in court, there never was any question in my mind as to his insanity. His symptoms were in accord with a certain type of insanity which he had neither the experience nor the mental power to feign successfully. It can not too often be insisted on that a lunatic, like a sane man, may fuss, or feign, or fight, or lie, or, in short, may commit any offense against righteousness or the law. The existence of sanity or insanity must be decided altogether independently of any considerations as to the moral obliquity of the individual, except in so far as this directly elucidates his insanity.

About eleven years ago in one of the interior cities of Pennsylvania a man was tried, convicted and executed for shooting another man who had attempted to enter his house to serve a writ, or in some way to carry out some form of legal process. The man who committed the homicide had barricaded himself, somewhat after the fashion of the sixteenth or the seventeenth century or earlier, as detailed by more than one novelist. This man's family and past history, the extraordinary views which he held as to his rights and wrongs, the manner in which he committed the crime, his conduct before, at the time, and after the killing were among the evidences of his probable insanity. Many things in his history pointed to a long-existent paranoid state with maniacal episodes.

Feigning was asserted in this case, and there was some evidence to support the idea that the accused had shammed some things during his confinement. Simulation, whether present or not, was not inconsistent with the form of insanity from which he was supposed to be suffering.

Like Taylor, he gave a dramatic exhibition in court which inclined some of those who observed it to the view that it was feigned, and others that it was simply the impulsive act of a man of unbalanced mind under great excitement. While his son, a young boy, was testifying, he suddenly jumped up, and before those about him realized what he was doing ran toward the witness-box, calling out the name of his son. The latter ran as his father approached, and an interesting scene was presented of a chase of a boy by a man and of a man by the officers who soon caught and restrained him. Apparently the incident was not premeditated, but the result of a sudden impulse.

In the case of a Chinaman recently tried in Philadelphia and convicted of murder in the first degree, the question of simulation played a most important part. It was urged by the medical witnesses for the prosecution and combated by those for the defense. As this paper has already too much expanded, and as this case has not yet been heard on appeal, it is perhaps not desirable to discuss it at length. I may take the opportunity at some future time of presenting it more fully. A mere statement, however, of a few of the facts in the case will be of interest in our discussion. The accused was only about 18 or 19 years of age and had shot a man whom he scarcely knew, and with whom he had had no quarrel. In our discussion of simulated insanity the case was especially interesting with regard to the confusion of theatrical behavior with feigning; reference to this point has already been made. The case was also one in which careful investigation indicated that the type of insanity present was such as could not have been successfully feigned by any one who had not a considerable knowledge of psychiatry.

In the examinations made by the witnesses for the defense in this case the prisoner again and again said that he heard voices, that the voices told him to kill the man whom he had shot, or that he would be killed himself. He declared over and over again that the voices told him that he was the greatest of all Chinamen and that he was the prophet of Confucius. These assertions were frequently repeated in a most emphatic and sometimes a dramatic way. He arose from his seat in great excitement on several occasions, declaiming the statements with violent gesticulations.

The accused regarded himself as not only a great man, but also as one who was persecuted; as a sort of martyr and hero. He strutted into the room and around it in an extraordinary manner, with his legs drawn together or partly crossed.

A word or two might be said about those cases in which verdicts of a second degree or of some degree of manslaughter are brought. Such findings are usually in the nature of what might be termed compromised verdicts. Juries which are doubtful as to sanity or insanity, or which desire for other reasons, as because of the so-called unwritten law, bring in such verdicts when often it is quite clear that these should either be one of murder in the first degree or of acquittal on the ground of insanity. In nearly all such cases the plea of insanity is set up because the law does not seem to provide any other.

In one case in which I was a witness many years ago, the jury brought in the ridiculous verdict of involuntary manslaughter in the case of a man who had with premeditation shot and killed another man who had had illicit relations with his wife while he was away from home on business. Although the plea of insanity was entered in this case, nobody in the court room nor in the community seemed to worry much either about the plea or the verdict. The man on trial did not feign insanity, nor was it necessary for him to feign this or anything else.

A second-degree verdict was reached in the case of a man who shot and killed another man whom he believed to be the paramour of his wife, and also shot and wounded his wife. This man did not simulate insanity, but seemed to regard the plea with contempt. Nevertheless, there were facts in the case which pointed decidedly to the view that he had delusions of marital infidelity.

In another case, a young woman who had been for a short time a patient of mine was tried for shooting and killing a man with whom she had become in some way entangled. This young woman, whose people were respectable and honorable, had been a source of great anxiety and distress to her father and the rest of her family from her childhood. She was wayward, seemed to have no moral sense, and committed many outrages against propriety and even decency; she was at times depressed and apathetic and at others irritable and excited. She had not, however, presented signs of insanity which could be readily marshalled in her defense. My counsel, both to her father and to her attorneys, was not to employ experts and so bring on a conflict between the district attorney and those who were employed to defend her, but to endeavor, if possible, to get a second-degree verdict. Whether as a result of this counsel or not, this course was followed, and practically by agreement a second-degree verdict was given and she was sent to prison for many years. In this case there was, so far as I know, not the slightest attempt at feigning, but rather a condition of stolid indifference on the part of the accused.

Recently I was called on by the prosecutor of pleas, with the approval of the judge, in a city not far from my place of residence, to examine with another physician into the mental state of a man who, while in a state of drunkenness or temporary mania or both, had shot his father and mother, one of whom had died. The man had been in prison for several months, was perfectly sane, and in a comparatively good physical condition at the time of examination. His manner was frank, he did not make the slightest effort to simulate insanity, and, as was learned from the prison officials, he had made no such attempt during his incarceration, and had been in every respect a well-behaved prisoner. The only light on which to act in reporting on this, as on some other cases, was that which could be obtained from the life history of the accused man. This pointed clearly to chronic alcoholism of a serious sort. He had begun to use alcoholic beverages when a child, and as years progressed had resorted to them, with increasing frequency, changing from the lighter forms of beverage to those of a stronger kind. He had had episodes or periods of excitement and probably had had hallucinations of sight and hearing at some of these times. These and other facts led my colleague and myself to the opinion that at the time of the motiveless shooting he was probably suffering from temporary mental disorder and was not fully cognizant of the act or of its consquences. A second-degree verdict was given and the man was sent to prison for life. All sensational elements were wisely eliminated from this case by those who conducted it, its management affording a good example of the manner in which such cases should be investigated.

In only five or six of the cases thus hastily analyzed and reviewed in which simulation was alleged or inferred was there in my judgment any evidence supporting this idea. In two of these cases the individuals were really insane, but indulged in violent behavior which may or may not have had an element of shamming in it. In three of the cases the simulation, although suspected, was certainly not demonstrated.

1909 Chestnut Street.

ABSTRACT OF DISCUSSION

Dr. Alfred Gordon, Philadelphia: I can voice the sentiment and ideas expressed by Dr. Mills in regard to the rarity of the simulation of insanity in hospitals. I was connected as examiner of the insane with the Philadelphia Hospital and detention ward for several years, and out of thousands of cases I never saw a case of simulation of insanity in psychopathic wards. So far as private practice is concerned I have had some experience in courts and in treating patients also. I have come across a certain number of cases in which the diagnosis as to whether insanity was or was not present was in doubt; but these cases are extremely rare. In my opinion, in the majority of instances of true insanity, the diagnosis can be established only after prolonged and repeated examinations. There is no special difficulty even in court cases, in cases of homicide, to establish whether true insanity exists or not. For this, however, frequently repeated examinations are necessary.

There is only one form of mental disturbance in which the alienist or neurologist frequently hesitates, namely, in the amnesias. In a recent case which occurred in Philadelphia a man committed homicide and then attempted to shoot himself; a bullet entered his brain and remained there; and the question of establishing the existence or non-existence of true amnesia was extremely difficult. The patient was able to give an account of everything that occurred up to the moment of the homicide, but he was absolutely incapable, apparently, of remembering anything concerning the homicide or the fact of his shooting himself.

When an *x*-ray picture was shown him demonstrating the presence of the bullet in his head, he wondered; he could not understand how it was possible, he said, that a man could carry a bullet in his brain and be alive; he could not admit it; and the question consequently which came up in court as to whether the man was a true criminal or whether there was a real amnesia present, was an extremely difficult one.

Dr. Mills spoke almost exclusively on the subject of the frequency of the occurrence of simulated insanity; I had hoped to receive from him some suggestion as to what are the true signs by which we can establish the question of the existence of simulation of insanity or not. It is difficult to lay down certain rules which would be a constant guide in determining the question of insanity. But one thing is certain in this class of cases and that is that these patients should be put in the hospital and observed repeatedly and for a long time before a diagnosis is made.

Dr. T. Diller, Pittsburg, Pa.: Dr. Gordon has referred to rules which would enable us to detect the simulation of insanity. I do not suppose any certain rules could be given by any one. I believe that the only way that simulation of insanity can be detected is through our general knowledge of the subject. My experience is entirely in accord with that of Dr. Mills; I have seen but one clear case of simulated insanity. This case, which occurred two or three years ago, was that of a man who was found guilty of murder and had been sentenced to be hanged. No claim of insanity had been put in at the time of the trial and none after the trial until a certain day when the prisoner was supposed to have become insane suddenly; and the insanity was supposed to have come about in this way: He went to bed as usual, having acted in the ordinary way the day before and given no suspicion of insanity. The next morning the keeper went to the cell and found the man mute. He was entirely mute and remained so up until the time Dr. Hutchinson and I examined him two or three weeks later—I don't know just how long. We went into the jail and the man was standing in the middle of the cell with his head moving from side to side and in a rhythmical way, and when the keepers made an attempt to go toward him, as they approached him he would offer to bite them. On being ordered to do certain things he would always do them after he was told three or four times; though he would never do them the first time.

There is a certain something that comes to one in seeing a patient like this that can hardly be conveyed in words, but the whole picture convinced us that the man was simulating. The points were these briefly: mutism occurring suddenly is a great anomaly. I did not know of any insanity of that sort. Mutism occurring with motor agitation was the second suspicious point. The third point was his always doing things, *i. e.*, after he was told three or four times. Fourth, the general dramatic effect of attempting to bite these keepers coming up to him in the way he did; finally, he refused to eat with his hands, but ate his food directly with his mouth out of plates that were brought to him. We were entirely convinced that it was a case of simulated insanity. Physicians in the town were of a different opinion and when they knew of our report they sent in a petition to the Governor protesting; and then they did a thing that I was very glad they did do, a thing that we might have done but did not do—they gave the man ether and when he came out of the ether he talked loud, long and continued to talk so that it made the test absolutely convincing.

I may say in passing, although the point has nothing to do with the scientific side of the question, but to show what troubles we poor neurologists and alienists experience, we sent in a very moderate bill of $100 each for our services, a sum which I am almost ashamed to mention before New York and Philadelphia neurologists, and a great controversy arose between the county and state authorities as to who should pay the bill. The question was debated exhaustively, many letters passed back and forth, and finally I received an opinion from the attorney-general of the state saying that no law covered this subject; that he was extremely sorry but that he would see that a special bill was introduced in the legislature providing for our fees. This was done and just at the time $9,000,000 had been spent for the capitol, and to keep down expenses within proper bounds these fees were cut down to $75 apiece.

Dr. L. L. Uhls, Osawatomie, Kan.: While in general I agree as to the rarity of these cases, yet I am convinced that almost every man of large experience has seen one or more of these cases of simulated insanity. An interesting case came to our institution. A man had been tried for forging checks. It was decided that he was insane and he was sent to us. He came apparently suffering from melancholia with agitation, insisting that some one was going to harm him. I thought recovery was rather suspicious. Within two weeks he told me how much better he was feeling, thanked me for treatment, and said he was sure he was going to get well. At the end of six weeks I notified the sheriff that there was no excuse for holding the man longer. He took him back and he was put on trial. The defense called in five local physicians in the little town, all of whom qualified as "experts," who testified that the defendant was insane. The accused sat in the court room during the trial apparently in a great state of excitement, and kept crying out, "I know what you are going to do, I know you are going to kill me!" I was asked to appear as an expert in that case and I stated that I believed he was a criminal, that he understood that he had committed a crime and was trying to so conduct himself as to be acquitted of that crime on the grounds of mental derangement; that I believed he ought to go to the penitentiary and not back to the hospital. The jury decided that the man was insane and he was ordered back to the insane hospital. But he hated that so badly that he took French leave, disappeared, and has never been heard of since.

Warden McClaughry of the Federal penitentiary at Leavenworth had a prisoner who, he thought, was simulating insanity. He called in an expert. They did everything they could to find out the true condition. The man was accused of a serious crime and the warden decided that he was simulating. But the man was so clever that his actions indicated that he was insane. He would eat his own feces and drink his own urine day after day and week after week, and do many other things as remarkable as that. Finally the expert made the suggestion that the case should be discussed in the presence of the prisoner and this was done. The expert said "this man is in a serious condition, and I know of nothing that will do any good except to open up the head and examine the brain; it will probably kill him, but he is a goner if we don't do it, and there is about one chance in 700 if we operate on his head that he may live." They began to prepare the patient for operation, when he gave up, and he said: "Hold on, gentlemen, I have been making this up. No surgery for me!"

Dr. Pearce Bailey, New York: The question of the correlation of the crime with the supposed mental state has not been touched on. Crimes committed by the paranoiac are characterized by cunning, while those committed by epileptics are characterized by brutality, with multiplicity of blows and mutilation of the victim; and the man who does the deed ordinarily makes no effort to escape. In like manner, the crime of the alcoholic is often committed with any instrument that happens to be handy. And the failure of correspondence between the character of the crime and the feigned mental condition would excite suspicion as to the genuineness of the mental symptoms. In New York the majority of criminal cases with mental symptoms are quickly disposed of by a commission and the individuals do not appear for trial at all; they are sent without trial to one of the institutions for insane criminals.

Consideration of the motive is important from a legal point of view. There was tried in New Jersey a number of years ago a man named Wood, who without any motive that could be demonstrated, killed an old farmer with whom he was driving in the country. The murderer told a remarkable story to the effect that he had no recollection of ever having seen the man, much less killing him, and had no recollection of where he was during that time. The diagnosis lay between psychic epilepsy and shamming. There were no evidences of insanity so the lack of motive brought a compromise verdict, the man being sentenced for life. Since he has been in prison he has given no evidences of insanity.

This whole question should be discussed from the point of view of limited responsibility. It is rarely possible for a conscientious alienist to say in so important a question as this that a man is absolutely feigning; most criminals are defective. The decision as to how far their defects affect their responsibility is one that generally has to be decided by a compromise verdict.

Dr. F. W. Langdon, Cincinnati: It may be of interest to add to the cases reported four cases that I recall. In two the patient was charged with murder. In one, the man, who was a foreigner, an Italian, claimed he could speak no English. He had been arrested on a country road a mile or two from the place where a burglary had been committed; lying apparently sound asleep with the loot lying around him, under a tree. On being brought into court he exhibited exaggerated actions and much volubility. His lawyer was anxious for me to declare him insane, but I remanded him for further observations, which proved that the man was shamming; whereon he was indicted and convicted.

In the second case a man was trying to escape the consequences of a misdemeanor by feigning insanity. The examiner cunningly remarked in a subdued but audible tone of voice to a bystander: "That fellow does not look crazy. They usually roll their eyes around more and move their hands and feet, and do not sit so still as this fellow does." Acting on the suggestion almost immediately, the man began to roll his eyes and move his feet. This man's shamming was readily revealed.

Two individuals charged with homicide and feigning insanity, were of considerable interest. One was a clerical gentleman, who, it was alleged, had murdered a young girl. While in the general hospital he certainly simulated primary dementia very well; so cleverly was it done that for a long time there was doubt as to the diagnosis. Privately, I was inclined to think he was malingering, for he overdid his part sometimes; but when the alienist for the defense testified in court that the prisoner had dementia; and when the alienist called for the prosecution testified that the prisoner had been simulating when he first examined him some months before, but he believed that "prolonged simulation had carried him over the line of sanity into dementia," he was found insane, committed to a state asylum where he remained a year or two, making altogether too much improvement as I thought, until one day he escaped and was never heard of again. The presumption, therefore, is that he was feigning, and I must confess that he was a good actor.

The fourth case was that of a man who walked into a jail with a shotgun, stuck it between the bars and emptied the contents into a prisoner. I was called by the prosecution to answer a hypothetical question as to his sanity. This man ran out, warned everybody to be careful, and acted in an agitated manner, tore his hair, but he never failed to eat, sleep, etc. My testimony was that the evidence did not show insanity. He was convicted of murder and sentenced to a long term, but I heard recently that he was pardoned within a short time.

Dr. George A. Moleen, Denver: This subject strikes this Section as a discussion on appendicitis used to strike the Section on Surgery. No question is more interesting to the majority of us. Recently in Denver we have had a little festival of crime, and this has given rise to a wave of insanity which has had its immediate starting point with the crime. The title of the address as given in the program raised a doubt in my mind as to whether it was the successful simulation of insanity or attempt at simulation which was meant.

There is no doubt but that in a number of cases which we have had in Denver recently the accused have attempted simulation. One of these which I had occasion to observe on several occasions before the court, was a woman of 54, who had been perfectly well previously and who took particular pains to secure her re-election as treasurer and custodian of a fund known as the Children's Hospital Fund, which was inaugurated by a local newspaper. About the time the monies were to be utilized she had misplaced the funds and they could not be found, and the theft amounted to something like $3,000. She was accused of embezzlement, but immediately took sick and became mentally broken. I examined her at her own house where it had been reported that she was unable to be seen, and that she was unable to appear in court. I went out unknown to examine her and while she was stated to be in bed and not to have partaken of any nourishment for some time, I found her fully dressed, even including her shoes, stockings and underclothes, and well-nourished. When I entered the room she was perfectly quiet, exhibited no nervousness, no trembling, no fear, and very little anxiety. However, within a few minutes after my mission was stated she became violent, screaming that I was sent there as one of her persecutors and that I intended to kill her. My associate was asked if he was going to kill her; and other points were brought out such as delusion that some lady had come up there and cut her throat, and that her fingers were dripping with blood, and that as a result she would be forced to wear gloves for the rest of her life. She stated that she was in the hospital and would soon get well; that she did not know where she was; and with other evidences of confusion she said that she was born in 1867 and that she was 67 years old, and a great many other points that she gave me as an evidence of dementia or rather amnesia. In the court room an interesting point was brought out: she was placed on the stand and in reply to questions where she was stated that she was in the hospital. The prosecuting attorney asked her if she had any recollection of the monies. She said "Monies, monies, I don't know any monies," and reached into her pocket and handed him a small purse. She was then removed from the stand by her attorney, a large attorney weighing about 200 pounds, and her husband, who firmly grasped her under the arm pits and led her to a chair in front of the dock. She then began to tremble all over and hurled herself down and succeeded in getting to the floor. Of course there was considerable uproar in the court and every one said she had fainted and that the doctor should be called. But her face was quite florid owing to the muscular exertion necessary to enable her to get away from these two stout men.

The points briefly in this case were of those 57 different varieties, so to say, and I do not believe could have existed in true insanity, and her actions were attributable to a desire to deceive the court and impress the jury at the time of the trial.

Dr. Charles K. Mills, Philadelphia: In the brief time at my disposal of course it was impossible for me to discuss the methods of unmasking simulation; but these methods have been well presented in the course of this discussion. I still hold to my original statement that simulated insanity is rare. It certainly is, in private and hospital practice. I have not had a large experience in prisons, and none in criminal lunatic hospitals like the one at Auburn.

The conclusion at which I arrived regarding insanity in prisons was that there were many more cases of insanity in prisons which were not regarded as cases of insanity than there were individuals simulating insanity. With regard to the cases reported in the discussion as instances of simulated insanity there might have been some little difference of opinion as to one or two of them at least. I do not believe, on the whole, that the plea of insanity in homicide cases is so frequently abused as it is supposed to be, if the cases in which the so-called unwritten law comes into play be omitted from the calculations, and perhaps some cases of alleged alcoholic insanity. Probably more individuals are executed who are insane than are saved from execution by the plea of insanity.

ABSTRACT OF DISCUSSION ON THE PAPER OF DR. ALBERT H. MILLER

[DR. MILLER'S PAPER BEGINS ON PAGE 1353 OF THIS ISSUE]

Dr. J. A. Stucky, Lexington: Any method which simplifies anesthesia diminishes the quantity of the drug used and the dangers that attend its administration is to be hailed as a great advance. I have contended, and still do contend, that the patient should be practically from under the influence of the anesthesia by the time the operation is finished to insure rapid recovery. This can be facilitated by the administration of a small dose of morphin hypodermically—⅛ to ¼ gr. with from 1/150 to 1/200 gr. atropin. I rarely give more than 1/6 gr. of morphin. I am glad Dr. Miller used the term "charging the patient with ether;" I have used the word "soaking." Charging the patient with any anesthetic is dangerous. Chloroform is a dangerous anesthetic in any adenoid or tonsil operation, and especially when there is a tendency to the status lymphaticus. I believe the ideal method has not yet been devised, unless this method suggested by Dr. Miller proves so to be. Rectal anesthesia, as advocated by Cunningham, has its advantages. I have used it only eight or ten times and have not had the opportunity to develop the idea as it has been carried out elsewhere. In some places the technic has been very much improved, and I believe that by this time next year we will probably hear some results with rectal anesthesia that will startle us. This method is nearer the ideal method because the anesthetist and anesthetic are nowhere near the field of operation. It appeals strongly to me. For several years I have used with satisfaction vaporized ether through a long rubber tube attached to the ether bottle and worked with an ordinary atomizer bulb. Another method which I saw used in London a year ago is a modification of the method shown by Dr. Miller in which the metal ether tube is incorporated in the mouth gag. I have used that with gratifying results. I have used the nasal tube once and do not think I shall ever use it again.

Dr. J. O. Roe, Rochester: The point regarding the warming of the anesthetic is a good one. I invariably warm it and find that I can get better results with about one-half the amount of ether or chloroform than when they are used cold. The anesthesia is quicker and it is not necessary for it to be so profound, nor for the patient to be so thoroughly saturated with the anesthetic. The dangers of anesthesia and particularly of chloroform, in the operation for adenoids and enlarged tonsils, are due to the greater readiness with which respiration is cut off when these obstructions are present. This is the reason why death sometimes occurs and is not, unless in rare instances, due to the condition called lymphatism. In these cases the child is unable to breathe through the nose, so that when the anesthesia becomes so profound as to abolish the reflexes, the tongue drops back over the larynx and the child is unable to breathe. In administering an anesthetic in these cases, it is, therefore, of the utmost importance to open the mouth widely, to pull the tongue firmly forward, and to raise the angle of the jaw. By thus keeping the breath way free and not carrying the anesthetic so far as to abolish all reflexes, as is so often done, we eliminate the dangers of anesthesia in these cases.

Dr. C. F. Welty, San Francisco: Prior to a year ago I used the nasal tube exclusively. A tube devised by Rupert I have used for the past year and find it the most satisfactory that I have tried. I think this new apparatus is a further improvement on that because of the fact that one gets the vapor directly into the tube, which will concentrate the amount of anesthetic given. I begin my anesthesias with nitrous oxid, and after the patients are completely under I change to the warmed ether. It is better to have it warmed because the ether is taken up more rapidly. This new apparatus seems to be the most improved thing on the market to-day. The greatest difficulty in doing tonsil operations under general anesthesia is to keep the patient breathing properly at all times. I have used a tongue depressor and at the same time pulled the tongue forward which, seems to facilitate matters.

Dr. Sylvan Rosenheim, Baltimore: It seems to me that what we need at the present time is not so much the apparatus as the man behind the apparatus. We need professional anesthetists, such as they have abroad. At every hospital there should be a professional anesthetist; it is especially important in this line of work. Recently at one of the hospitals with which I am connected there have been two deaths, each undoubtedly due to the anesthetic. The operation was done skilfully in each case but the patients ceased to breathe. In neither of these cases was an autopsy obtained. An injection of adrenalin chlorid, a small amount, had been used, and in view of the case which Dr. Harris recently reported in which death occurred after the injection of adrenalin for removal of the tonsils, it might be just possible that that may have had something to do with these fatalities. Ether was the anesthetic employed in both cases.

Dr. M. P. Rupert, Philadelphia: I have been very much interested in Dr. Miller's apparatus which is probably an improvement on mine. I don't quite see, however, why Dr. Miller doesn't find the heated vapor more advantageous, because I think one can carry on a more even anesthesia with less ether and less after-irritation with the warmed vapor. My experience has been that there is less mucus secreted with the warmed vapor than with the cold.

Dr. J. A. White, Richmond, Va.: I have always had difficulty in keeping such patients properly anesthetized so that I made an apparatus very similar to this but cruder. Some time ago, however, I began to resort to rectal anesthesia in long operations about the face or throat, and do not expect to go back to any other method in such cases because in my hands it has proved so satisfactory. I have never encountered any objection on the part of a patient because, as a rule, my patients never know I use it. I prepare them by giving a purgative early on the day before the operation, followed by an enema the same night and another the next morning. I anesthetize them in the usual manner by inhalation and continue the anesthetic by the rectum. Of course, the patient being under the influence of the anesthetic has no idea how it is kept up afterward. Any one who tries the method will not go back to the other way. One does not have to stop at any time; however, I have always had a professional anesthetist give my anesthetics for me.

DR. B. R. SHURLY, Detroit: Rectal anesthesia requires, first of all, an expert anesthetist who has been trained in that particular manner of giving anesthetics, and unless the vapor is properly passed into the rectum there is considerable danger of burning the mucous membrane and causing a serious and deplorable state of affairs. With an expert this method has been successful in the hands of a few.

DR. A. H. MILLER, Providence: I have investigated the question of warmed ether thoroughly and have not been able to find any apparatus that properly furnishes a warmed vapor. The different forms of apparatus are for the purpose of vaporizing the ether, but the vapor is practically all at the same temperature. With this apparatus, after passing the ether through five feet of rubber tubing at the room temperature, it is practically the same temperature as is produced by applying heat. The advantages of the apparatus are, of course, the possibility of giving a large quantity of ether and having perfect control of the anesthesia at all time. The advantages of the gag are that it is not in the way of the operator and that it does not become dislodged. I have used it over a thousand times and it has never yet been dislodged.

FINAL RESULTS IN CONSERVATIVE SURGERY ON THE OVARIES*

JOHN OSBORN POLAK, M.Sc., M.D.
BROOKLYN

The meagerness of the literature on conservative surgery on the ovaries, when these organs are the seat of neoplastic formations, has prompted me to analyze the cases in which I have performed operations in the last nine years, and of which detailed records, noting the pelvic conditions and symptoms at the end of one and two years, have been kept.

Do the remote results of conservative surgery on a diseased ovary warrant us in resecting such an organ? This is the question which the surgeon must answer daily, at the operating table. On the one hand, ablation in a young woman has many unfortunate physical and psychical results; while the preservation of a part of one or both ovaries renders the symptomatic cure of the patient uncertain, and a secondary operation may be necessary.

The reasons which have been advanced in favor of conservatism are, first, the preservation of the ovarian function (i. e., that of ovulation and possible pregnancy, and the retention and maintenance within the body of the ovarian secretion); second, the avoidance of the artificially produced menopause, with its troublesome nervous phenomena. Many patients, for sentimental reasons, refuse operative relief, because an oöphorectomy must be done to get it.

Are the first two reasons of sufficient importance to compensate the woman for the frequent recurrence of her pain, and the ever-present possibility of further cystic changes, and the necessity of subsequent operation? In 1903 the late Palmer Dudley presented a paper before this Section, based on a study of 269 cases of his own (in which the left ovary had been resected in 130 cases, while the right had required resection in 141), together with the 2,212 cases of other operators, reported to him in personal communications.

In this paper he concludes that conservatism is justifiable, because it maintains and retains the menstrual function. No mention, however, is made of the exact pathologic condition of the ovary which required the resection. Neither is there any mention of the final results of the operation.

In a study of 1,970 cases of resected ovaries, abstracted from the literature, I find records of but thirty-two known pregnancies. Hyde, in concluding his admirable and scholarly paper on this subject, says: "Pregnancy does not occur as often as thought; in fact, it occurs in not more than 5 per cent. of the patients operated on in this way." Again, all resected ovaries present the possibility of a recurrence. Hyde's incomplete records show that about 5 per cent. of the patients return for subsequent operation. The avoidance of the artificially produced menopause is the only result that resection can absolutely promise. Some years ago, in a paper read before the Brooklyn Gynecological Society, in which I reported 161 conservative operations, I called attention to the disappointing symptomatic results of ovarian resection, and I believed then, as I do now, that the field of ovarian resection is a very limited one. There are ideal and selected cases, in which conservatism may be practiced.

A study of the records of 300 cases, occurring in my personal service, in which resection was done, with the large number of secondary operations necessitated, has afforded me a wider insight into the pathologic conditions which follow on resection, and thus permits me to make some practical deductions. This series shows that forty-one patients have returned for further operation; or over 12 per cent. of the entire number operated on by conservative methods since 1901 have required ablation of the remaining ovary, or the part of the resected ovary left at the primary operation.

Twenty-six pregnancies have occurred in the 240 women who could have become pregnant, or in over 10 per cent. of the women operated on, which is a higher percentage of pregnancies than generally reported. One patient contributed three full-term pregnancies and two abortions to this list.

This fertile patient, though included in a previous paper read before the Brooklyn Gynecological Society six years ago, is entitled to further mention, as she exemplifies a type in which conservatism may be used with some certainty of success. I refer to the ovary which is the seat of a monolocular-cyst. This patient was 18 years of age at the time of her primary operation, and had suffered since puberty from premenstrual and menstrual dysmenorrhea. Both ovaries were cystic and prolapsed; the left, on section, showed numberless small cysts throughout, and was removed. The right contained one large cyst the size of a lemon, destroying the entire cortex. This was resected by a wedge-shaped excision, leaving only a fringe of the hilum, .5 cm. wide and 2 cm. long. Both tubes were left undisturbed. This patient has been attended by me in all her pregnancies. She has menstruated regularly and, while there is no enlargement of this remnant of ovary, it is tender and causes some premenstrual pain at this period. During the past year the catamenial flow has become scantier, and the patient is beginning to complain of the nervous phenomena which suggests an approaching menopause.

In all the patients (except the forty-one returning for reoperation) an early operative menopause has been averted, and 106, or more than one-third of the total number, are free from pelvic pain of any kind, menstrual or intermenstrual. These patients have been carefully examined repeatedly, and their pelvic findings recorded. In twelve of this number the "treated" ovary is larger than one would suppose it should be, but has occasioned no contiguous inflammation and has produced no symptoms.

---

* Read in the Section on Obstetrics and Diseases of Women of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

In eighty-one women both ovaries were resected by the excision of a wedge-shaped piece of ovarian tissue, which included the diseased structures. The ovarian wound was then closed with a fine catgut suture, great care being taken to have all hemorrhage controlled and dead space obliterated, with just sufficient tension to obtain coaptation without constriction, which I believe to be the cause of many failures. This was illustrated at the secondary operation in two instances, which will be cited later.

In 219 of the women making the basis of this report one ovary was entirely removed and the other resected after the method described above. It is interesting to note that seventeen of the twenty-six pregnancies recorded followed ablation of one ovary, while the ovary producing the fertile ovum had been extensively resected. Further, so far as my pathologic records can be followed, but two patients who were fortunate enough to become pregnant presented microcystic ovaries at the time of operation. This bears out a contention which I have made on previous occasions, and concurs with Hyde's views, i. e., that a microcystic ovary, sufficiently diseased to cause pain or invalidism, is better removed, as conservatism in this class, as Gordon wisely states, consists in "conserving the woman's health, not in preserving a diseased organ."

The results of attempting to preserve a diseased ovary when it is the seat of multiple microcystic degeneration are illustrated by the following case, which may well stand for a type:

A. H., aged 23, admitted to my service in the Jewish Hospital, married, sterile, had always suffered from severe premenstrual dysmenorrhea, which had become worse since her marriage. She also complained of a profuse mucopurulent leucorrhea. The smear from the cervix showed gonococci. A median abdominal incision disclosed a double hydrosalpinx, with a cyst of the left ovary totally destroying the organ. Both tubes and the left ovary were removed. The right ovary presented a multiple cystic degeneration, the cysts varying in size from that of a pea to that of a bantam's egg. The cystic portion was freely excised, leaving only a narrow strip of the ovarian hilum, apparently free from any cysts. Postoperative recovery was uncomplicated: On examination one year later, the patient stated tnat her menses had recurred regularly, lasting two days, but of small quantity, preceded by severe pain in the right side and swelling of the breasts for two weeks before each period, and that all marital relations had occasioned severe pain. On bimanual examination, the uterus was found in normal position, with its mobility limited on the right side and posteriorly. The right ovary was the size of an orange, painful and adherent.

Of the forty-one patients who have returned for further surgery on their adnexa, all but three present similar histories and findings. All resected ovaries swell and become markedly enlarged during the first month after operation, but this swelling gradually subsides under the influence of time, rest, and the establishment of an equalized circulation. This latter can be obtained only by careful suturing of the ovarian wound without constricting it, and by placing the resected ovary high in the pelvis, in order that the return circulation may be favored, and further, that it may be free from peritoneal contact until such time as its wound is closed over, for peritoneal adhesions make painful ovaries.

If the return circulation is impeded by the misplacement of sutures, the cystic formation is very rapid and extensive, as was instanced in two of my reoperations, which were done within two weeks of the primary section, and in which the remaining ovary was found in the cul-de-sac, markedly cystic and adherent.

The primary section in one case had been made by one of my assistants. Both tubes had been removed by a running suture along the top of the broad ligament, and the right ovary resected by a wedge excision of several cysts. The bleeding was troublesome, and in attempting to control it the circulation was interfered with by the too frequent insertion and too tight application of sutures. The ovarian engorgement was further increased by the omission on the part of the operator to suspend the uterus in order to keep the resected ovary high in the pelvis. Too much can not be said on this point; the ablation of the tubes, with or without the removal of the ovary, will always shorten the broad ligaments, and so pull the uterus out of and back of its normal position; or when one ovary and tube are removed, the uterus will be drawn backward and to one side, unless counterbalanced by some procedure which will hold the uterus in place.

On examination of these patients before dismissal from the hospital I noted the uterus displaced backward and to the right, and a large cystic mass the size of an orange in the right posterior cul-de-sac. On reopening the abdomen, it was seen that the sigmoid had become adherent to the anterior face of the fundus, and that the uterus was retroverted over a large cyst of the right ovary, densely adherent by fresh adhesions in the cul-de-sac. The size of the cyst surprised me.

The findings in the second patient were almost identical with those just described; the adhesions were freed and the ovary removed. Before closing the abdomen the uterus was suspended; the subsequent recoveries were uneventful. I am convinced, from my secondary operation findings, that many recurrences of cysts or of pain about the tumor (or on the other side after one ovary has been ablated) are due to omission to secure the resected ovary high enough in the pelvis to maintain an equalized blood supply, and to failure to keep the wound surface free from omental parietal and intestinal adhesions, which may be accomplished if the uterus is raised by some of the many retroversion operations. Even when a uterus is in normal position before operation, removal of part of the adnexa will shorten the broad ligaments, and will retrovert it to some degree, enough to start the vicious cycle. Both tubes were removed in sixty cases in the course of this series. When a double salpingectomy is made, it is my custom to suspend the uterus, no matter what its previous position may have been. This step, I believe, does two things: it minimizes the adhesions of the omentum and the intestines to the stump, by encouraging adhesion to the parietal peritoneum; and it maintains the ovary in a better position for its circulation.

All of these operations were in child-bearing women. In 119, but one tube was ablated; and both tubes were left undisturbed in 121, leaving 140 women in whom future pregnancy was a possibility. The tubes were ablated; the uterine portion of the tube was excised by an elliptic incision about the tube into the cornua, exsecting most of the intramuscular portion; and the free portion was cut away. The muscular gap thus produced was closed with interrupted catgut sutures, and hemorrhage from the ligament controlled with a running suture along the top of the broad ligament, which technic, I believe, helps to retain the length of the broad ligament.

Notwithstanding this careful technic, one patient became pregnant in the cornua of the uterus, and developed an interstitial pregnancy, which has been reported elsewhere. This case has not been included in the report of the pregnancies following on resection of the ovary, as it occurred in one of the sixty patients in whom both tubes had been excised.

No attempt was made to preserve any portion of a diseased tube by resection or the phimosis operation. When a tube was found diseased it was removed, as my former experience with conservative procedures on the tubes has been most disappointing.

A study of the class of ovaries resected will perhaps lead to conclusions of value. In 163 cases pathologists' reports are noted. Of this number, ten patients had simple retention cysts, due to thickening of the wall of the capsule, resulting from long prolapse of the ovary. Of these, three were treated by simple puncture with the cautery, with the following end-results: One is cured of all pelvic trouble. Two have tender and enlarged ovaries, though one of these women has been pregnant. In the remaining seven cases, the ovaries were resected and the patients made perfect recoveries. Six patients had dermoids; the tumor was excised, and the remaining stump of the hilum preserved by careful suturing. One of these women has returned for reoperation for a unilocular cyst, developing from the retained fragment.

In case of papilloma, unrecognized clinically at the time of operation two years ago, a papilloma of the resected ovary subsequently developed, with papillomatous peritonitis-ascites and hydrothorax. The patient was operated on again and has made a good primary recovery. Seven large multilocular cysts, varying in size from that of an orange to that of a child's head have been enucleated from their laminated walls, which were trimmed down and sewed over, leaving a resected portion of an ovary 3 to 4 cm. long and 1 cm. wide. No recurrence has taken place; the ovary has atrophied, menstruation has continued normally, and one pregnancy has resulted.

Forty-seven patients had cysts of the corpora lutea, which had increased the weight of the ovary sufficiently to make it prolapse and to cause menstrual and intermenstrual symptoms; in all cases the ovaries were deeply resected by wedge-shaped excisions. Thirty-six patients are free from pain and menstruate regularly and painlessly. Four have required further surgery; two have a small, cirrhotic and painful ovary as a result. Five complain of menstrual pain without any physical change in the organ.

Two primary fibromata of the ovary were enucleated from their capsules, the excess of which was cut away and sutured, so as to make a small mass of ovarian tissue. Both the patients have been lost track of. In the remaining ninety cases the diseased structures belong to the class of multiple cystic ovaries, presenting numberless small cysts throughout the ovarian structure. In fifty-five of these cases one ovary was ablated, leaving one good ovary, while thirty-five were resected.

The extent of the involvement in each ovary was determined at operation by an incision through the organ from cortex to hilum, laying it open for inspection; the entire cystic portion was excised, and the remaining fragment carefully sutured with fine catgut. But five complete cures are recorded, twenty-one patients have returned for further surgery. Nine menstruate regularly, though the quantity has become scantier each year, and each period is attended with some degree of menstrual pain.

Two pregnancies followed resection in this class. It would seem, therefore, that multiple cystic degeneration was least favorable to conservative procedures, while ovaries containing retention cysts, cysts of the corpora lutea, large monolocular cysts, fibroids and dermoids, may be conserved by resection, with considerable hope for the patients' continued well-being.

287 Clinton avenue.

ABSTRACT OF DISCUSSION

Dr. John G. Clark, Philadelphia: Several years ago, when the question of conservatism came prominently into the foreground, many of us felt extremely enthusiastic as to the outlook. We had all seen the disastrous effects of a surgical menopause on very young women, and yet ovariotomy was the common procedure in those patients suffering with suppurative conditions incident to the gonococci which commonly attack younger individuals. In some of these the surgical menopause was so infinitely worse, so far as its effect on the individual, than the original disease, that the second condition was far worse than the first. We looked, therefore, with happy anticipation to the elimination of the infection through salpingectomy and the conservation of the ovaries. Unfortunately, our hopes were not realized, for an operation in the midst of an acute gonorrheal infection is usually followed by most disagreeable sequelæ, such as progressive suppuration and, ultimately, a second operation or very serious invalidism. I have therefore been forced to the conclusion, as the result of practical observation of a large series of cases, that an operation in the midst of an acute inflammatory disease is more likely to be successful, so far as actual relief of symptoms is concerned, if radical rather than conservative. However, we have recently had brought before us, particularly by Simpson and others, the value of withholding operation until the acute process has passed and merely the pathologic débris remains. This recalls the classic observations of Saenger, than whom there was no greater or more acute observer, with reference to the residuum of disease. He particularly laid stress on the fact that the so-called chronic adherent ovaries and tubes were not the seat of infection, but were merely the derelicts of the gonococcal storm. In some instances, the destruction has been so extensive that nothing less than a radical operation will suffice; in others conservatism may play a splendid rôle. Conservatism as I view it at present, therefore, does not relate so much to the operation as it does to the time for the election of the operation. In all acute inflammatory conditions, unless symptoms are most threatening, I withhold operation until the acute inflammatory process has passed, and the patient is largely free from pelvic symptoms. Then one may perform the abdominal operation with the view to removing the residium of the inflammatory attack, leaving behind all structures which having been involved are now well, or which have not been invaded by the attack. In this way I have secured results which are infinitely better than those which followed operation in the midst of acute infection.

Dr. Polak has, I believe, put before us another phase of this question, namely, that pregnancy, which was formerly a chief mainspring in considering conservatism, need no longer be considered, for the majority of women who have suffered from inflammatory diseases had been and will still remain sterile. The conservation of ovarian tissue is done with the sole purpose of perpetuating menstruation and preserving that occult influence which is ascribed to the ovarian secretion. This is of the greatest value, not only from merely the sentimental, but also from the physiologic standpoint. Every woman under these conditions may hope for maternity, whereas with the complete cessation of the period this hope is lost and she is very likely to become morbidly introspective and chronically neurotic.

Dr. Howard A. Kelly, Baltimore: This subject has been a burning question with us for many years, and it is interesting to note how our attitude relative to a particular question will change in the course of years. By conservatism now we mean diseased ovaries, and yet I doubt a little whether Dr. Polak does not include cases which we do not consider diseased at all; those cases of small cystic formation. My experience in the past twenty years has been that conservatism has a more and more limited field. We all went at it as Dr. Clark has said with a great deal of enthusiasm when it came to us like a new idea that we might save some of those structures which our predecessors were sacrificing. There is an age limit in conservatism, and there must also be considered race and condition. There is the working-woman who insists above all things that she must be well. Speaking of conservatism in a broad general sense, I believe it will depend on the condition of the surrounding structures and on the previous history of the patient. If there is history of long-continued suffering and of invalidism for years, I am more apt to be radical there than to conserve. It depends, too, on the point of view of the patient. I am willing to be conservative if the patient will take the brunt of what will come in the way of relapse. As a matter of fact, I find the patient leaves the decision to me. If the patient says: "I want above all things menstrual function and the chance of conception," then I do everything I can, putting the burden in the way of relapse on the patient.

In regard to the Graafian follicles, unless there is very decidedly clear ovarian tissue, it is a mistake to leave a mere shell of an ovary. Unless the patient insists I would hardly recommend leaving structures which were under suspicion on the opposite side having malignant disease on the other. After removing a dermoid cyst from one side I have split the other ovary and taken out one or two dermoid cysts. I believe we ought always to do that if the opposite ovary is enlarged. What shall we do in pelvic inflammatory disease? In many of these cases an ovary is held down under a web of adhesions and is in bad company. The tube is pouring out its infection and if we take out the tube, with that the disease, and free the ovary from its adhesions, I think we can safely be conservative. But, when the ovary has been bound down under old adhesions, I think it ought to be cleared out. When the ovary is retained my plan is to have it held up from the pelvic floor.

Dr. A. Goldspohn, Chicago: This subject has been a favorite one with me for many years; and if I am not mistaken, I was the first to publish anything about resection of ovaries west of the City of New York. I have often been attacked in my position; sometimes by men who were serious, but oftener by theoretical quibblers. Those who were serious from practical experience I respect, but the others scarcely deserve any notice. Nagel of Berlin once made series of sections of ovaries and declared that these follicle cysts as a rule contain ovules, that therefore they are all healthy, and that resection of ovaries is uncalled for. This astonishing declaration aroused numerous other equally qualified men to investigate the subject by even more extensive examination of series sections of such follicle cysts; and they all disagreed with Nagel's declaration, saying that the ovules were not present usually, in a normal condition, and that the pathologic nature of the follicles is established both histologically and clinically. Nagel never appeared in defense of his position.

This subject requires the best of our gynecologic acumen. We gain in judgment by experience, and in my opinion it is the supremest test of an operator's judgment to tell chiefly by palpation what is healthy ovary tissue, or how diseased it is, what may we risk leaving and what we ought to remove. It is not the size of these bodies that determines or indicates their health; it is consistence more than anything else. Furthermore, I am guided in this matter by considering the natural destiny of Graafian follicles, namely, to come to the surface and rupture. Normally they do this before they become enlarged to the size of a hazel or hickory nut, as we often see them. If they do become so enlarged, there is something pathologic which has either prevented their rupture, or has caused their overgrowth or hydropic condition; and whether we need to meddle with them or not, will depend partly on the size of these cysts, and more on the thickness and density of the structures overlying them and interfering with the rupture, which is needed to relieve the painful tension in the organ. Again, there are gnarly cirrhotic parts of ovaries, in which all glandular structures are gone, but nerve endings remain in continuous compression, causing much pain, not merely local, but often referred to other organs in the same part of the body, that need to be removed. Of course, such surgery, and in fact all surgery on these parts, is out of order when the tissues are in a state of acute inflammation. That must have subsided. Then only can we tell what really needs to be removed. And, as the opposite policy is correct, with reference to the appendix, appendicitis in women should be cared for by the gynecologist, because he is most likely to make the important differential diagnosis correctly.

Dr. R. Hall, Cincinnati: I think Dr. Kelly emphasized the real points in saying that it is not conservatism if experience demonstrates that in retaining the ovary the gynecologist does not cure his patients. If one removes an ovary and the ovary on the opposite side has a large cyst, possibly the size of an orange, that ovary should be resected and the patient left a portion of the organ. I have to my credit three or four patients, like the one mentioned here, who have borne children afterward. One patient whom I mentioned once before in this Section was over 40 years of age, the mother of one child. Ten years previously a tumor weighing 30 or 40 pounds and a cyst larger than a large orange were removed, leaving about half of an apparently healthy ovary. In eighteen or twenty months afterward she bore a child, for which she and her husband were very grateful.

It is a question whether it is conservatism in cases in which a cyst is removed and there are multiple cysts in the other ovary if one leaves that ovary. In a few such cases in which I have left the ovary the patients have returned with the symptoms all exaggerated and a secondary operation must then be done. Papers with carefully recorded cases like Dr. Polak's will throw light on the subject and give us a better working plan. For twenty years I have worked along this line myself, keeping careful record of cases, and have come to the conclusion that conservatism in saving the ovaries has a limited field. I believe, however, that in the class of cases mentioned in the paper, operation may be done after the acute stage has subsided. Frequently one is obliged to remove the ovary and the tube involved in the suppuration, but in the majority of instances one can save the ovary by liberating it and removing the tube, cutting it well away into the uterus. The woman is left with a practically normal ovary. This can be attached to the round ligament in a higher position than normal. While the woman may not bear children she retains the function of menstruation. If there is any conservatism in saving the ovaries it is in this class of cases, and it is rarely that such patients return for removal of the ovary.

Dr. C. C. Frederick, Buffalo: During my operative experience of over twenty years, I have been imbued with the idea of conserving for every woman on whom I operated as much ovarian tissue as possible with the view of maintaining menstrual function and the better degree of general nervous tone which ensues as a result of that conservatism. As Dr. Clark has said, we all know the mental condition of patients with total ablation of the ovaries, especially in young women early in the menstrual life. But the older I grow, and the more work I do, and the more results of conservative surgery on the ovaries I see, the more inclined I am to be more radical, especially in cases in which the disease in the ovary is primary. In cases in which the ovary is infected because it is in bad company with its corresponding tube, and especially in infection of the ovary by extension of the inflammatory process, I think by getting rid of the tube and then treating the ovary, if it be abscessed, by exsecting the abscess and cleaning out the pyogenic membrane and cauterizing with carbolic acid or the electric cautery, one can leave that ovary with tissue that will continue to functionate and it will give no further trouble. But when the ovary is primarily diseased in one part, you can make up your mind that if the diseased process has not already attacked the other part of the ovary it will eventually do so. The more I have seen of results of conservative surgery in cases in which the disease is primary, the more inclined I am to take the ovary out *in toto*. I have seen many recurrences in this class of cases. Recently a woman came back to me who had been operated on ten years ago. She had multiple cyst of one ovary and a monocyst of the other. At that time she expected to be married and was anxious that the operation should be conservative. Ovarian tissue about two-thirds the size of an ordinary ovary was left. She was in good condition and menstruating six months after the operation. I never saw her again until last week I was sent for and found her a poor, pale, emaciated being in bed with a great big tumor. I found that she had had recurrence of the ovarian tumor which she had neglected. Carcinomatous degeneration with adhesions had ensued and the case was hopeless. I could not take out the tumor without taking her life on the table.

Dr. P. A. Harris, Paterson, N. J.: The routine practice of removing ovaries with diseased or inflamed tubes is absolutely prejudicial to all interests involved. Of all the cases of pus tubes which come to operation, it is in exceptional instances only that both ovaries are so involved as to require their removal. The Fallopian tube is the natural habitat of certain inflammations. The ovary is also sometimes inflamed, but it is always an unwilling participant in the inflammations which ordinarily affect the tubes. When we consider how decidedly dissimilar are the tube and the ovary, both in structure and function, we have a theoretical argument which should sooner have taught us the fallacy of assuming that the ovary is a willing participant in the inflammations which so commonly involve the Fallopian tubes. I am convinced that in not more than 4 per cent. of all cases in which salpingectomy is required will it be necessary to remove both ovaries. I feel sure that 97 per cent. of all women from whom I have removed pus tubes that menstruation continued, and that the removal of the diseased tubes cured them of such pains as resulted from the tubal infections, and that it has been the rule after the removal of the tubes for the patients to return to their normal menstrual habits. Primary dysmenorrhea or the pain with menstruation which existed before the infection of the tubes has not been cured by removal of the tubes. Only such pains as were added to the primary dysmenorrhea by the inflammation of the tubes have been cured by removal of the tubes.

One per cent. and possibly 2 per cent. of women from whom we exsect diseased tubes may have some further trouble due to infection of a remaining ovary. When abscess develops in the ovary in such case it is very easy to cure it by vaginal section and drainage. I think menstruation should be preserved for every woman from whom we remove diseased tubes. An exception might possibly be made for women who have suffered from very painful menstruation from childhood. I wish to say that, in my experience, while the exsection of pus tubes has generally cured the patient of all pains which came to her after she acquired the infection, such operations had little or no effect in affording relief from dysmenorrhea, which occurred and continued from puberty. Such dysmenorrhea is only curable by the removal of the ovaries.

Dr. J. O. Polak, Brooklyn: I think that Dr. Hall received a wrong impression from the paper; I do not condemn the preservation of the ovaries in inflammatory cases, but I condemn resection in the presence of inflammatory conditions. Nor do I operate on these patients during the acute stage by the abdominal route. I make vaginal drainage and wait weeks or months before doing anything further, and in that way I am able to save ovaries. All of us who have done obstetrical work and have followed these postpartum infections know what time will do in Nature's efforts to protect the woman and conserve her organs.

Restriction of Diet in Children's Diseases.—E. Feer, Heidelberg, in an article in *Pediatrics*, states that a very difficult and unsolved problem is how far may one proceed with the starvation period. One often swerves in the doubt between the sins of commission and the sins of omission. When the nutritional conditions of the child are still moderately maintained and when it can still draw on its energy for nutriment, one need not fear instituting a starvation period.

THE TREATMENT OF PUERPERAL INFECTION

A STUDY OF THE CASES TREATED DURING THE LAST FOUR YEARS *

THOMAS J. WATKINS, M.D.
CHICAGO

This report comprises 61 cases, nearly all of which were treated at Wesley and St. Luke's hospitals. Most were cases of severe infection, as the mild cases are usually not referred to the hospital. A number of the patients had been curetted once or twice, had had intra-uterine treatment, had become worse and were sent to the hospital. Twenty-eight of them had a temperature of 103+. In 33 cases the temperature was less than 103; 28 of the patients had an inflammatory exudate in the pelvis. This is the same number that had a temperature of 103+, but there were 9 with pelvic exudate with a temperature of less than 103. Six patients had suppurative peritonitis.

Blood examinations were made as a routine in all the cases. The leucocyte count varied from 5,000 to 58,000, and there were very few that were of any great amount of interest. The increase in the leucocyte count was generally in proportion to the amount of febrile disturbance. In one case the white counts were especially interesting in that the patient did not develop a leucocytosis until she had been in the hospital for about two weeks, although she ran continuously a very high temperature. She had a large pelvic exudate and a profuse purulent vaginal discharge. The slow development of the leucocytosis was probably due to the virulent infection and the low physiologic resistance. The patient showed very little tendency to improve until the leucocytosis developed, when the improvement was rapid. The white blood count varies so generally with the febrile disturbance that it is of very little practical value in a large percentage of the cases. A low count with a high temperature, however, indicates a low resistance or a virulent infection, or both, and is of some value in the prognosis. A continuous diminution of a leucocytosis indicates recovery. The white count is also of value at times in the diagnosis, especially where coincident or complicating pathologic conditions are present.

Bacteriologic examinations to determine the variety of the infections were not made in many cases and were usually disappointing in results. Gonococci were found in only three cases. Bacteriologic examinations, it seems to me, are often unsatisfactory, and the findings as yet are of no practical value in the treatment. This is especially true, as different strains of the same infective organisms may vary as much as do the different bacteria.

COMPLICATIONS

There were the following *complications:* Iliopsoas abscess (non-tuberculous), 1; pyemic abscesses, 1; pneumonia (lobular), probably embolic, 5; phlebitis, 2; intestinal obstruction, 1; acute nephritis, 2. Many of the cases, however, had some albumin and occasional casts.

TREATMENT

The treatment employed is somewhat routine. A careful history is taken and a complete physical examination made. If the fetus is still *in utero,* miscarriage unavoidable and the cervix not dilated, the uterus and vagina are packed with sterile gauze. This is done irrespective of the amount of temperature. It is left in from

twenty-four to forty-eight hours, depending on the results. It is repacked if there is not sufficient dilatation to empty the uterus without much traumatism. It is not uncommon to have the gauze, fetus and secundines expelled spontaneously. If the fetus has been expelled, the uterus is explored to see if it is empty, if indicated by the presence of hemorrhage or offensive uterine discharge, except under conditions mentioned later. If there is no hemorrhage or offensive uterine discharge the uterus is considered empty. It is possible but not probable for it to contain some secundines in the absence of hemorrhage and offensive discharge, but in this event if left alone the discharge will soon become offensive. If the uterus is small and well contracted, even in the presence of a slight offensive discharge, it is not explored. The uterus is explored and emptied, preferably with the finger. It is probably a conservative statement that one can never be perfectly sure that all tissue is removed from the uterus except by digital exploration. The statement is often made that the entire cavity cannot always be reached with the finger. My associates and I believe that with an anesthetic and pressure from above the entire cavity can be explored with the finger.

To pack the uterus and allow it to empty itself is always good treatment, and is especially good treatment even with a dilated cervix to be employed by the inexperienced or to be used where the surroundings are unsuitable for surgical work. The harm resulting from retention of some of the secundines has been very much overestimated. There is not such an urgent demand for their immediate removal as would be indicated from the literature. This is well illustrated by the experience of dairymen. Cows often have retained placentæ: they become infected and offensive, but they are always expelled spontaneously about the ninth day, and they apparently never cause death. One should treat an infection in the uterus much as one would an infection of the hand. One would not scrape, tear and cauterize sloughing tissue on an infected hand; one is no more justified in doing so in the uterus. In either instance all decomposing and sloughing tissue should be removed that can be with little or no traumatism; otherwise it should be left to separate spontaneously.

The finger may be aided by *placenta forceps* or a large curette; the preferable instrument, I believe, is the placenta forceps. One may quite easily mistake with the finger the rough surface where the placenta was attached for retained tissue. This may also be grasped with placenta forceps and be mistaken for some of the secundines. If one uses a curette it should be as large as can be conveniently passed through the cervix, as a large curette is less dangerous and much more efficient.

After the uterine cavity is emptied no more intrauterine treatment is indicated and it is left alone. An intrauterine douche is always dangerous and is practically useless. There is very little objection to wiping out the uterus at this time with gauze, but this is probably of very little value. There is no indication to use any drain, as it will drain itself. The use of gauze in the uterus would interfere rather than facilitate drainage and it always increases decomposition. Better drainage is accomplished by elevation of the head of the bed. If there is any infection about the vulva, a wet dressing is kept over it to prevent coagulation of the discharges and thus to facilitate drainage. No vaginal douches are used; they often do harm, can not possibly be of much service; the nurse will usually introduce more infection than she will remove, and they are disturbing to the patient. After all that has been said against the use of douches in these cases, physicians quite generally employ vaginal douches frequently and often subject the patients to the dangerous intrauterine douche.

There has been much said about the "protective leucocyte wall" that is formed in the uterus in cases of infection and of the importance of not disturbing this by curettage, treatment, etc., but I believe that enough has been said about the thrombi that close up the uterine sinuses, which readily become infected and often produce serious trouble by being dislodged with intrauterine treatment. In cases of pelvic exudate my associates and I seldom explore the uterus even if there is some suspicion of retained tissue, as these cases are especially liable to be made worse by intrauterine manipulation.

The peritoneum is considered to be involved when there is pain; absence of pain usually means absence of peritoneal involvement.

The uterine cavity was explored in only 16 of the 61 cases, and the uterus and vagina were packed with gauze for the purpose of emptying the uterus in 8 cases. In 31 of the cases the only treatment employed was the use of means to build up the physiologic resistance.

The supportive treatment consisted chiefly in building up the physiologic resistance. The routine of it consisted in the following:

1. Forced nutritious diet.
2. Attention to elimination.
3. Relief of pain.
4. General hygienic treatment, especially fresh air and sun baths.

INDICATIONS FOR SUPPORTIVE TREATMENT

Much attention was paid to the building up of the physiologic resistance in all of the cases, and in 16 of the cases with a pelvic exudate it was the only treatment used. After excluding the necessity for exploration of the uterine cavity or after the uterus has been emptied, the patients were put on this treatment. This treatment was then continued if the patient improved. In the great majority of cases in which the patients were very ill they were put on this treatment as a test to determine whether the tendency was to improve or do otherwise. As soon as it seemed certain that the tendency of the case was to get worse we resorted to more radical procedures except in hopeless cases. We learned, however, that in a number of the cases the patient would have recurrent attacks of fever lasting for a few days and then would go on to recovery. This occurred in a number of cases in which there was a large pelvic exudate. In some of the cases the exudate extended down to the side or posterior to the vaginal canal, and in some the exudate extended upward as high as the crest of the ilium and nearly to the umbilicus.

Our knowledge as yet has given us nothing that is so valuable in the treatment of puerperal infection as the building up of the physiologic resistance. In the cases of pelvic exudate or suppuration the systemic infection is much more important than the local infection. In a majority of the cases the exudate or the pus will become sterile in two or three weeks without operation. With operation there is little or no hope of shortening the duration of the febrile disturbance, and in cases of exudate there is considerable probability that the duration of the infection will be increased by incision and drainage, as this is very liable to result in a secondary infection. *The serum treatment of puerperal infections has* proved as yet to be of no value.

My associates and I believe that resistance is best increased by nutritious diet, and for this purpose milk, beef-juice and eggs were chiefly depended on. An ice-bag is placed over the abdomen for the relief of pain and it may have some local value. Much care is given to see that the patient sleeps six or eight hours out of the twenty-four. Codein or morphin is given in sufficient quantities to insure rest and generally in sufficient quantities to relieve pain. Fluids are depended on chiefly to stimulate elimination. If patients do not take two quarts or more by the mouth in each twenty-four hours salines are given by the rectum. We occasionally use the drop method with the foot of the bed raised in the very bad cases if postural drainage is not indicated. We believe this to be especially indicated in cases in which the tongue is dry, those in which the stomach is disturbed and those in which the kidney excretion is small. Sun baths and fresh air were given in abundance. We have been especially careful not to disturb the patient by treatment, for we believe that the cheerful state of the patient is of extreme importance, as it aids much in giving them an appetite, in the digestion of food and in procuring sleep. In the majority of cases of puerperal infection the body will develop an immunity or will destroy the infection in the course of two or three weeks with the above outlined treatment.

Vaginal section was made in eight of the sixty-one cases. Three of the cases of vaginal section had suppurative peritonitis and were fatal. In the other five cases section was done after the supportive treatment alone failed to give desired results and was used more frequently in the earlier than later cases.

Abdominal section was done in three cases. In one case of abdominal section a solid exudate was found involving the right broad ligament, the right ovary and tube, the appendix and the head of the cecum. This was done after the very acute symptoms had subsided when the condition of the patient seemed to be at a standstill. The operation was entirely explorative and it was found impossible to remove the inflammatory mass *without* doing great injury to the intestines. The patient went on to complete recovery and the mass had entirely disappeared when she left the hospital. In one case the section was for intestinal obstruction, and in the other secondary to vaginal section and drainage in a case of gonorrheal infection. There were six cases of suppurative peritonitis and they were *all fatal*. *Three of them* had vaginal section and drainage. Abdominal section was made in none of them, as the condition of the patients was so serious that it seemed to offer no hope.

LENGTH OF TIME IN HOSPITAL

This was as follows:

One week or less, 21 patients. This included 6 fatal cases; none with pelvic exudate.
One to two weeks, 20.
Two to three weeks, 9.
Three to four weeks, 2.
Five weeks, 21.
Six weeks, 3.
Seven weeks, 1.
Eight weeks, 1.
Nine weeks, 1.
Twelve weeks, 1.
Patients with pelvic exudate average twenty-five days.

This gave an average of sixteen days for all cases and an average of a little over seventeen days for the patients that recovered. In six of the seven fatal cases the patints died before they were in the hospital one week.

Fifty-four patients recovered and seven died. Eight of those who recovered had a slight thickening at the site of the exudate on leaving the hospital. Two of them went home with some exudate before the febrile disturbance had entirely disappeared. One patient had a considerable mass two or three inches in diameter in the region of the left ovary and tube at the time of leaving the hospital. She was advised to have an abdominal section, but declined.

DEATHS

One patient had a general suppurative peritonitis and died in a very few hours after admission to the hospital. She was so ill that there was very little treatment given. One other patient came in in nearly the same condition and died in twenty-four hours. Four other patients had general suppurative peritonitis and died in a few days after admission to the hospital. In three of them we made vaginal section and drainage, which was of no value. These six patients were so ill that recovery seemed hopeless. One died after a vaginal section and drainage. She was admitted to the hospital with a large pelvic abscess, which was opened and drained through the posterior vaginal fornix. She improved for a few days, when a second abscess formed, which was opened up through the old sinus. Slight improvement occurred after this, but a general suppurative peritonitis followed and death resulted. It is possible that an abdominal section in this case with a radical operation would have resulted in recovery. The patient died on the twentieth day after admission to the hospital.

Patient 2 was interesting, as she developed an iliopsoas abscess. There was no tuberculosis, but there was a colon bacillus infection. The abscess was drained through an incision in the posterior vaginal fornix. The patient made a complete recovery, without any injury to the joint.

Patient 7 was interesting, as she developed a pelvic abscess secondary to curettage. She was admitted to the hospital on account of a very severe hemorrhage; very little tissue was found in the uterus; the retained secundines were probably passed in the blood clots. It is quite probable that she would not have developed an abscess if she had not been curetted.

Patient 59 had intestinal obstruction due to an exudate involving the pelvic colon. The obstructive symptoms disappeared after freeing the intestine. The patient had numerous attacks of dilatation of the stomach when one to two quarts of liquid would be washed out of the stomach. She also had an embolic pneumonia. We have been surprised at the infrequency of secondary colon bacillus infection in the cases of pelvic exudate. In none of the cases did there seem to be any indication for ligation or excision of thrombosed veins.

The amount of medication used in these cases has been comparatively small. We seldom use stimulants of any kind and believe that alcoholic beverages are seldom of use and often do much harm. We have given no tonics except occasionally, and then only with the hope of increasing the appetite for food. There is no evidence that the use of ergot to produce uterine contractions is of any value. It increases the danger of displacement of the infected thrombi in the uterine sinuses, and there is no special value to be expected from uterine contractions. The bowels are usually moved by the use of saline enemas and occasionally by the use of purgative enemas. It is not found necessary to give cathartics very often by mouth. We are thoroughly impressed with the belief that the treatment generally employed for puerperal infections has not kept pace with the advance in the knowledge of the pathology and bacteriology of these infections and that it is still influenced by a woeful amount of meddlesome and dangerous traditions.

CLASSIFICATION

It will be noticed in the tabulated report that there is no classification in the treatment of sapremic and septicemic cases and of the infections before and at term. I believe that such classifications confuse a study of the subject and are of no practical value. The mistake is often made of considering some cases as local and others as systemic infections. Infections with putrefactive bacteria are often considered sapremic or local infections and infections with other bacteria as systemic infections. There is fever in both varieties of the infection, and that means that there are bacteria and toxins in the blood in both instances, which could always be demonstrated if our tests were sufficiently delicate. Bacteria and toxins in the blood mean systemic infection. Putrefaction bacteria are often associated with other bacteria; and even non-pathogenic bacteria under certain conditions may become pathogenic. There is no anatomic, physiologic or pathologic reasons for any distinction in the treatment between infections before and at term.

These cases have helped to teach us that the systemic infection is much more important than the local infection and that the systemic treatment is more important than the local treatment; that the most important systemic treatment consists in supporting and increasing the physiologic resistance; that the infection, like most bacterial infections, will last until an immunity develops; that this immunity will vary with the variety of the infection, with the virulence of the variety and with the resistance of the patient; that there is more danger of doing too much than too little; that it often requires more courage to avoid radical procedures than to perform them; that the energetic local treatment generally used is more dangerous than the infection.

103 State Street.

Contagiousness of Tuberculosis.—Montano, the celebrated physician (1550) declared tuberculosis to be one of the most dangerously contagious and most easily contracted of diseases, and an equally strong advocate of the theory of contagion was the anatomist, Morgagni (1682-1771), who would never perform autopsies on those who died from tuberculosis. —*Propaganda of the N. Y. State Charities Aid Association.*

THE CARE OF THE TUBERCULOUS AT THE FREE DISPENSARIES OF THE CHICAGO TUBERCULOSIS INSTITUTE

WITH SPECIAL REFERENCE TO THE USE OF TUBERCULIN AS A DIAGNOSTIC AND THERAPEUTIC AGENT

JOHN RITTER, M.D.
Instructor in Medicine, Rush Medical College; Physician in Charge of the Chicago Tuberculosis Institute Dispensary Rush Medical College
AND
CLARENCE S. WHEATON, M.D.
Associate Physician at the Dispensary of the Chicago Tuberculosis Institute at Rush Medical College
CHICAGO

Not since the earliest history of medicine or from the beginning of that period when tuberculosis began to be recognized as a distinct disease has such general and heroic onslaught been attempted to stamp out or check the growth of consumption as is being made at the present time in every civilized community. At the present day the medical profession in general is making a most vigorous campaign on the 'white plague" and in medical circles and association meetings various papers are frequently read and discussed on the prophylaxis, treatment and prevention of consumption. The legislatures of most of our states are establishing state sanatoriums for tuberculosis. Here in this city the Chicago Tuberculosis Institute has for many years undertaken, alone and single-handed, this almost hopeless and prolonged fight against tuberculosis. In order to extend its field of activity the establishing of a number of dispensaries in various sections of this city has been undertaken.

We shall try to explain how patients are received, treated, cared for, kept under observation, and looked after while they are enrolled as patients of the Tuberculosis Institute. The order of treatment and care of patients is, with probably very little modification, about the same at all of our dispensaries. The patient supposedly tuberculous is first received by a competent nurse, who interrogates him or her as to antecedents, duration of complaint, family history, previous ailments, environments, home comforts and surroundings, if sanitary or otherwise, the earning capacity of each member of the family, as well as that of the individual presenting, taking the pulse, temperature, respiration, weight, etc., all of which is most carefully noted on a specially provided chart, and after all questions have been satisfactorily answered, all answers noted down, the patient is then presented to the physician for examination. On the reverse side of these provided history charts are two representations, the anterior and the posterior aspect of the chest, and all pathologic thoracic findings are carefully indicated by the physician on these diagrams. Before the physician undertakes the physical examination he tries to elicit from the clinical picture presented an idea of what conditions or complications he may expect.

When all has been carefully tabulated and the examining physician has satisfied himself that the case is tuberculous the patient is given into the special care of the nurse and she visits each patient at his or her home, and usually at the following meeting, which is in three or four days, makes a report to the examining physician as to the home surroundings, what means can be furnished to the sufferer by his family or friends, what provisions will be made to make the sleeping-apartment as near to out-of-door living as is possible; also what friendly aid the patient's family is willing to give to both the patient and the workers in the institute. The nurse tries in all cases to impress on the other members of the family the paramount need of good wholesome fresh air, food, pleasant surroundings, cleanliness, all of which are essential in combating and arresting tuberculosis.

Everything being satisfactory, the patient is now furnished with a fever thermometer and a blank note-book, with printed directions, is taught by the nurse how to read the temperature, record and count the pulse, all to be carefully and accurately recorded in the note-book at least four times each day. We rigidly insist on the taking of the temperature and the counting of the pulse by each patient immediately on rising, before anything has been put into the mouth. These results must be accurately recorded in the note-book, as well as the subsequent results taken daily at 11 in the morning, 4 in the afternoon, and again at bedtime. Our patients are also required to note down daily in these books the amount and quality of food consumed at each meal, how they feel, and incidentally about the weather each day, and to note down what they do and what amount of exercise they take daily. We insist on regularity in taking nourishment, and very much deprecate the irrational stuffing method so much in vogue now. Following the ingestion of a wholesome breakfast, which should include one or two raw or soft-boiled eggs, a glass of milk, sufficiently well-buttered bread, bacon, cereals and fruit, if desired, no more shall be put into the stomach until the noon meal, and after a substantial noon repast nothing more until the evening dinner. A glass of milk with bread or crackers may be allowed at bedtime. Experience has taught that in this long-drawn-out fight of the body tissues for supremacy the stomach is much better prepared to aid in this struggle, to assist digestion, if a sufficient interval is allowed for rest between each meal.

Patients with positive findings at the very beginning of their enrolment are required to report at the dispensary twice each week and under no circumstances can a patient receive treatment or encouragement unless he or she produces the note-book, giving in tabulated form the patient's condition since the previous visit. From time to time our nurses at the dispensary again visit these patients at their homes to satisfy themselves that the physician's orders are strictly carried out, and should the members of the patient's family or the attendant show any negligence or any relaxation from this constant vigil, it is at once reported to the examining physician. In coping with tuberculosis we depend mostly on good wholesome and nutritious diet, pleasant environments, home comforts, sufficient rest, and an abundance of fresh air, the giving of medicines being of minor importance.

For some time the use of tuberculin in the treatment of tuberculous subjects in carefully selected cases without complications, given hypodermically in infinitesimal doses, has been followed by most encouraging results, and yet the promiscuous use of tuberculin in the hands of the inexperienced cannot be too highly condemned. When tuberculin is used at all, the patient must be under constant observation. Should this not be possible, then tuberculin must not be used. The physician must always remember that tuberculin is not an antitoxin, but a toxin, a direct poison, the product of the tubercle bacilli, and that the object of its use in minute doses is to stimulate the body tissues to the production of antibodies.

Tuberculin is used both for diagnostic and for therapeutic purposes. For diagnostic purposes, in small children we rely chiefly on the so-called Moro test. For children and young adults we use principally a 25 per cent. solution of tuberculin, making use of the so-called von Pirquet method of vaccination. For adults a subcutaneous injection of five drops or 1/3 c.c. of a 1 per cent. solution of tuberculin is used. Koch's old tuberculin, properly diluted, is used for both diagnostic and therapeutic purposes. These dilutions can very easily and properly be prepared by any physician possessing the necessary laboratory training. As accuracy is most essential in making dilutions of tuberculin, in order to insure uniform and proper dosage, measuring instruments, such as pipettes and graduates, are indispensable We will explain in somewhat extended detail how we prepare the dilution of tuberculin in use at our dispensaries.

Koch's O.T., 1 c.c., approximating 1 gram, is diluted with 0.5 per cent. carbolic acid in physiologic salt solution, making a 10 per cent. dilution of tuberculin; or to 1 c.c., O.T., are added 9 c.c. of phenolized physiologic salt solution. This is put into a bottle and labeled No. 0; of this 1 c.c. equals 0.1 gram, or about 1½ grain. Now the next or second dilution is begun by taking 1 c.c. from the bottle labeled No. 0, putting it into another sterilized bottle, and adding to it 9 c.c of the same phenolized physiologic salt solution, and the bottle is labeled No. 1. This gives a 1 per cent. tuberculin solution; each cubic centimeter equals 1 in 100, or 1 c.c. equals 0.01 gram, or about 1/6 grain. This dilution from bottle labeled No. 1, which is a 1 per cent. solution, is the one which we generally use for diagnostic purposes in adults by injecting hypodermically 5 drops. By taking 1 c.c. from bottle labeled No. 1 we prepare the dilution which is labeled No. 2, by adding to this 1 c.c., 9 c.c. of phenolized normal salt solution. This dilution, labeled No. 2, equals 1 in 1,000, or 1 c.c. equals 0.001, or about 1/60 grain. Again the dilution made by taking 1 c.c. from bottle labeled No. 2 and 9 c.c. of this same phenolized normal salt solution is designated dilution No. 3. Now, 1 c.c. of No. 3 equals 1 decimilligram, or for convenience 0.1 mg., or about 1/600 grain. No. 4 is prepared by taking from the above-mentioned No. 3, 1 c.c. and adding 9 c.c. of phenolized normal salt solution. Then 1 c.c. equals about 1/6000 grain, or 1 centimilligram, which again for convenience is better expressed as 0.01 mg. No. 5 is prepared from No. 4 in a similar way, each cubic centimeter of which equals 1 millimilligram (0.001 mg.), or about 1/60,000 grain.

Patients with pulmonary tuberculosis whom the examining physician considers suitable or selected to receive tuberculin as a therapeutic measure are treated by the hypodermic method by means of a specially provided syringe of 1 c.c. capacity divided into 100 parts. As we have no definite knowledge of the amount of antibodies possessed by any patient—neither his resisting power nor his tolerance for tuberculin—nor have we with our present knowledge of medicine any undisputed means of ascertaining either, it is advisable to be cautious, and in selected cases to begin by giving infinitesimal doses. We begin by injection in suitable cases with an initial dose of 0.05 or 0.1 c. c. from the bottle labeled No. 5, which contains the most diluted tuberculin preparation. This equals for the initial hypodermic injection 1/20 or 1/10 millimilligram.

It is generally stated that tuberculin should be used only in selected or suitable cases. What are selected cases, and when is a case suitable, and when not suitable? We consider as suitable all such cases which do not show a very marked variation in the temperature recorded during the twenty-four hours. A daily temperature not exceeding, at any time during the day, 99.5 may be considered suitable, remembering that a temperature above 99.8 to 100 is always unsuitable. An afternoon temperature varying very little from 98.8 to 99.5 is considered suitable to begin giving 0.05 to 0.1 c.c. from the vial labeled No. 5. The smaller the variation in temperature from the normal for the daily record, the better suited is the case for tuberculin treatment. It should always be remembered that in patients showing but very slight variation in temperature, possessing fairly good resisting power, which is usually manifested by a fair digestion and appetite, a fairly healthy appearance, refreshing sleep, absence of thoracic pain, the treatment should be chiefly hygienic and dietary, and that tuberculin for therapeutic purposes should not be administered. The object in using tuberculin is to stimulate the body tissues to greater activity in producing antibodies, thereby increasing the resisting power. Should this power be apparently sufficient to cope with the inroads of bacillary activity, then the use of tuberculin may cause an overstimulation, which should be avoided.

A case being considered suitable, as stated above, we begin by giving an initial hypodermic injection of 0.05 or 0.1 c. c. of the diluted tuberculin bottle No. 5. Should this injection be followed by a systemic reaction, as shown by headache, malaise, pains in the muscles, loss of appetite, increase in temperature, a second injection should not be given for at least a fortnight, after which another, about one-half the former quantity, may be used. On the other hand, should no untoward symptoms follow this initial injection, then after three or four days a second injection of double the initial dose, or 0.2 c.c. may be given. If none, or possibly a very slight reaction is manifested, then at an interval of three or four days a third injection is given, using 0.3 c. c. from bottle labeled No. 5; and we proceed in this manner until we reach as high as 0.9 c.c. of bottle labeled No. 5. One c.c. of bottle No. 5 being equal in tuberculin strength to 0.1 c.c. from bottle labeled No. 4, and in order to avoid using large quantities for injection, at our next treatment we give 0.1 c.c. from vial No. 4 and proceed as before.

It should be remembered that the treatment with tuberculin must be progressive and only in minutely increasing doses. Should a patient to whom progressively increased doses of tuberculin have been given show a rise in temperature after a number of injections, a rise above 99.8 to 100, further hypodermic medication must be discontinued until the temperature is again below 99.5, when we may continue our treatment by dropping back to about half the strength tuberculin dilution of the last injection given and carefully watch its results. Should this again be followed by a rise in temperature, we proceed as before, but again drop to one-half of the injection which was followed by a temperature rise. So also we observe that no injection should be given if at the seat of the last given hypodermic medication a little local reaction still lingers, manifested by an area of hyperemia, or if a nodule is plainly palpable under the skin. Tuberculin should be used cautiously, and in small doses only, to be discontinued if any reaction, either local or systemic, shows itself, be it ever so little. These progressive injections may be continued over periods varying from six to eighteen months.

When the administration of large doses has been reached the patients often show the beneficial effect of the medication. Body weight is increased, appetite and digestion good, temperature nearly normal for the twenty-four hours, and the general appearance is exceedingly good. When this stage has been reached we begin by giving a progressively descending medication, and gradually discontinue all tuberculin treatment when the patient's general health shows unmistakable evidences of arrested processes or possibly healed and cured lesions. The physician must always bear in mind that in all cases, either recent or chronic, showing great activity of the tuberculous invasion, in all hemorrhagic cases or such showing the slightest tendency to hemorrhage, as well as in all laryngeal cases, the use of tuberculin is vigorously contraindicated.

CONCLUSIONS

1. In cases of pulmonary tuberculosis without elevated temperature and low resistance, the proper administration of tuberculin is of undoubted efficacy.
2. Tuberculin is capable of producing great injury to the patient and this injurious influence calls for the greatest discretion in its proper administration.
3. There is frequently increased cough and expectoration following its injection. This, in itself, is not an untoward symptom. Tuberculin is an expectorant, *par excellence.*
4. Persistence of such clinical manifestation as general lassitude and physical weakness should cause the discontinuance of its administration.
5. In the presence of a mixed infection with high temperature incident thereto the use of tuberculin is inexpedient.
6. The opsonic findings in dispensary practice are impracticable at this time. Clinical study is absolutely essential in determining the size and frequency of the dose.
7. We caution against the use of tuberculin in advanced cases with positive findings. In this stage alarming results have followed its administration.
8. Tuberculin should not be administered to any patient unless it is possible to obtain an accurate daily record of the case.
9. Pulmonary hemorrhages are contraindications to the use of tuberculin, should slight hemorrhages manifest themselves during the treatment its use must be discontinued at once.

Clinical Notes

AN UNUSUAL CASE OF INSANITY WITH AN OBSCURE DIAGNOSIS

H. D. PURDUM, M.D.
Assistant Physician, Northern Michigan Asylum
TRAVERSE CITY, MICH.

The following case came under my observation during 1907 and 1908, and, as it showed such a variety of mental conditions, I thought it of sufficient interest to report:

Patient.—M. S., female, aged 33, single, born in Austria, was a domestic with common school education. Maternal and paternal grandparents lived to be over 70 years old. Mother and father are healthy and there is no history of alcoholic excesses, cancer, tuberculosis, paralysis, insanity or nervous diseases in the family. One brother had infantile convulsions but has been in perfect health since.

Past History.—M. S. was the second of four children, the rest of whom are in good health. Mother was 26 and father 24 years old at the time of patient's birth. Mother had a severe attack of typhoid fever just prior to patient's birth, but birth was normal and patient was free from sickness during the developmental period. She went to school seven years and reached the eighth grade. In disposition she was considered cheerful, sociable, kind, optimistic, ambitious and even-tempered. As a domestic, she held one position for years.

First Attack.—January, 1907, patient had an attack of grip, which lasted eight or ten days and from which she did not fully recover. In June following she felt so weak and run down she consulted a physician. He advised her to take a rest on account of the existing profound anemia. She did not stop work, however, but the week following the general feeling of exhaustion became so marked that it was necessary for her to take to her bed. After remaining in bed about ten days her relatives and friends noticed a mental change. She became irritable, apathetic and stupid. She also made queer statements, such as that she "had not brains enough to cry," etc. During the following four weeks patient was untidy; slept but little; took no interest in her surroundings; refused to answer questions or to talk spontaneously. She ate but little during this period and frequently refused food altogether.

Physical Examination.—On July 31, 1907, patient was admitted to this institution in a weak and emaciated condition. Her height was 5 feet; weight, 87¾ pounds. Pulse was 120; respirations, 22; temperature, 97 2/10; tongue coated; breath offensive. Bowels constipated and skin dry and scaly with acne eruption over back and face. Blood examination showed the hemoglobin to be 60; erythrocytes, 3,800,000; leucocytes, 12,000. Differential count: Neutrophiles, 58 per cent.; lymphocytes, 32 per cent.; large mononuclears, 4 per cent.; eosinophiles, 5 per cent.; basophiles, 0.5 per cent. and transitionals, 0.5 per cent. A catheterized specimen of urine was found to be negative, except for a marked excess of indican. No organic changes could be found in the respiratory, circulatory, digestive or generative organs, though the physiologic action of these various systems was very sluggish.

Examination of Nervous System.—Expression of the eyes was dull and staring; sight apparently unimpaired; pupils circular; left 3 mm., right 4 mm. in diameter. Both reacted to light and to accommodation. Hearing was apparently unimpaired. The senses of taste and smell could not be tested on account of the mute and negativistic state of the patient. Cutaneous sensations were tested with difficulty. Patient reacted to pain; also to tactile stimulation. Heat and cold were not reacted to. Deep reflexes were equally exaggerated on the two sides. Superficial reflexes subnormal. Romberg and Babinski signs were absent. Organic reflexes were not under the patient's control. There was some vasomotor paralysis, face and body being livid and the extremities cyanotic.

First Mental Examination.—Three days after admission an examination of the mental status was attempted, with the following findings: Patient was mute, resistive, untidy, negative and tube-fed. Her movements were stiff and awkward and she would stand in one position for hours, staring into space. When given attention she resisted and would often strike at the nurse. She kept up a rhythmical movement of the lower jaw. Sleep was insufficient. Speech, memory, orientation, delusions, hallucinations and school knowledge could not be tested because of the mute state of the patient. Consciousness was somewhat blunted, though patient appeared to have a clouded grasp on her surroundings. She associated to a limited extent, this being demonstrated when the examiner approached her with a pin. She also showed restiveness when taken into the operating room to be examined. The emotional feelings were blunted. Her facial expression was stolid and never changed. There was a general state of apathy with some irritability, when given attention. Volition was greatly disturbed and there was paralysis of the will. Occasionally she was impulsive, but most of the time, negative, mute and resistive, with associated hypermuscular tension. Social relations were greatly disturbed. Patient was difficult to care for because of her untidy and resistive state. A diagnosis of catatonic stupor was made on the basis of the above mental examination and anamnesis.

Patient remained in the institution for six months, during which time she gradually regained all her mental faculties and was discharged as cured. After leaving the institution she went back to her old position and did excellent work for six months; then became maniacal, which necessitated a readmission on July 23, 1908.

Second Attack.—The patient's affect on being readmitted was the opposite to what it was during her previous residence in the institution. On the first admission she was stupid, mute, apathetic, negativistic, untidy, and in poor physical health. At this time she was active, talkative, distractible and showed marked flight of ideas with some incoherency. Her physical health was good and she weighed 118 pounds.

Second Mental Examination.—This was made five days after the second admission: Patient had been in an actively maniacal state ever since being readmitted. She either sang, danced, laughed or talked incessantly. Occasionally she teased the other patients. On one occasion she broke out several window-panes. Her habits, on the whole, were good and her movements and speech were for the most part purposeful. She was perfectly oriented for time, place and person and consciousness was clear. Enunciation was loud and articulation distinct. School knowledge was in harmony with her opportunities. She wrote her name rapidly and the letters were large. Memory for remote as well as recent events was quite clear, except the period during which she was confined here on the previous admission. Of this she had but a hazy recollection. Hallucinations and delusions could not be demonstrated. The associative processes were very much enlivened and a marked flight of ideas with some looseness of thought connections was prominent. Patient was distracted by every new impression. Sustained attention was impossible. The emotional feelings were heightened and there was an exaggerated reaction to mild stimulation of the emotional sphere. The lower emotions were considerably involved. Feelings of hunger and fatigue were lessened. The sexual feelings were exaggerated. Volition was hyperactive and there was a marked pressure of activity with more or less purposeful movements. Mannerisms and negativistic states were not noted. Patient was constantly on the move and required considerable supervision. She was tidy in habits but careless of her general appearance. Occasionally her elation was beyond her control and she tore her clothes and disarranged the furniture in the ward. Most of the time her actions and speech were of a playful nature. Based on the above mental examination and physical state, a diagnosis of excited form of manic depressive insanity was made.

Course of Disease.—The above mental and physical conditions remained about stationary until during October, when patient became untidy, destructive, abusive and more or less violent. In November following the patient had one convulsion of the grand mal type, followed by stupor and mental confusion. November 20 she had six very severe convulsions, after which she was badly confused and clouded for two days. On November 24 patient had one slight convulsion. On December 15 patient was noticed not using her left hand, and when examined a neuritis of the musculospiral nerve was found. Her mind at this time was clearer than it had been for two months and she was able to assist with her personal care and the ward work. January 15 patient was very comfortable and quiet; had visitors and seemed to enjoy their company. Her movements were slow and somewhat retarded. February 15, patient was again destructive, violent and untidy and required special supervision. During the first few days in March the patient was quiet and well behaved. At noon on March 9 she began having convulsions and was not entirely free from them until 11:30 p. m. Her circulation became very feeble and edema of the lungs and brain caused her death at 4:30 the following afternoon without regaining consciousness.

An autopsy, though greatly desired, was refused by the relatives.

SUMMARY

There are several interesting features in this case to which I wish to call special attention.

1. The first attack presented all the cardinal symptoms of stuporous catatonia.
2. Complete recovery followed.
3. The second attack gave a clear picture of the excited form of manic depressive insanity.
4. The manic state was followed by a period during which definite delusions of persecution with violent and destructive tendencies were noted.
5. General convulsions of the grand mal type entered into the mental picture.
6. A short stage of depression, during which delusions of depression and retardation were the predominating symptoms.
7. Death was caused by epileptiform convulsions.

A true diagnosis of this case in my mind is difficult; in fact, I have never observed a case or seen one reported which presented so many distinct phases of mental aberration.

QUININ AND UREA HYDROCHLORID AS A LOCAL ANESTHETIC

ARTHUR E. HERTZLER, M.D., Ph.D.
Associate Professor of Surgery, University of Kansas
ROGER B. BREWSTER, M.D.
AND
FORD B. ROGERS, M.D.
Dispensary Assistant, University of Kansas
KANSAS CITY, MO.

In September, 1907, Dr. Henry Thibault,[1] of Scotts, Ark., published a short article calling attention to the local anesthetic effect of quinin and urea hydrochlorid. He recommended the use of a 1 per cent. solution for local injection and from 10 to 20 per cent. for local application to any mucous surfaces. Aside from this article by Dr. Thibault and one by E. J. Brown,[2] recommending its use in tonsillectomy, we have been unable to find any account of the use of these substances for anesthetic purposes in the literature.

For some six months we have been using this drug instead of cocain in all local anesthesias with the greatest satisfaction. So great has been the interest manifest in our studies by our professional friends that we have deemed it best to report our results up to date. Clinical experience was obtained in our private practice and by one of us (Rogers) at the dispensary of University of Kansas. The experimental work was done in the laboratory of the Halstead Hospital (Hertzler).

We started with the 1 per cent. solution recommended by Dr. Thibault. We found, as stated by him, that a perfect anesthesia is obtained which lasts from 4 to 5 hours. The anesthesia is more complete than with cocain. We soon discovered, however, that disturbances in skin union sometimes occurred. One of us (Hertzler) noted particularly that in hernia operations there was some disturbance in the healing of the skin wound which had not been noted after the use of cocain. The disturbance was not great, but the patient had to be kept in bed longer than after the cocain operation. The edges of the wound were indurated and thickened, but there was no pus formation. The thickening appeared to be due to cellular infiltration.

Hertzler thereupon undertook to determine experimentally the cause of the induration. Experiments performed on rabbits showed that the thickening was not due to cellular infiltration at all as was supposed on clinical grounds, but was due to a pure fibrinous exudate free from cells. This exudate was proved to be fibrin by Mallory's and Weigert's stain. The reaction appears, therefore, to be purely chemical in nature. The exudation of the fibrin begins to appear within a few minutes. In a general way it was determined the amount of exudate depends on the strength of the solution used; the attempt was made, therefore, to determine a strength of solution which would not cause this exudation of fibrin. In ½ per cent. solutions the exudate is less than with 1 per cent. and with ¼ per cent. solutions only traces can be discovered. To what extent this fibrinous exudate is subsequently converted into fibrous tissue has not yet been definitely determined, but apparently nearly all is absorbed.[3]

[2] Quinin Anesthesia, Painless Tonsillectomy and Adenectomy, THE JOURNAL A. M. A., Aug. 8, 1908, li, 496.

In order to determine the subjective sensations of the injection and to determine the question of a possible zone of hyperesthesia about the anesthetized zone, one of us (Hertzler) studied the effect by the injections in the skin of his leg. Injections of 1 per cent., ½ per cent., ¼ per cent. and 1/6 per cent. solutions and an injection of plain water as controls were used in each series. The 1 per cent. and ½ per cent. solutions gave immediate and complete anesthesia without a particle of pain during its introduction. Within a few minutes there was a distinct induration. With the ¼ per cent. solution, anesthesia was not complete for a few minutes, but was then as complete as after the use of the stronger solutions. The 1/6 per cent. solution gave delayed anesthesia, but after a few minutes was complete. In neither of these weaker solutions was induration noted on palpation. The water control caused intense pain on injection, and the anesthesia, at no time perfect, lasted only a few minutes. There was a zone of hyperesthesia one or two inches in width about the area injected. Curiously enough the hyperesthesia seemed to be for touch and not for pain.

The duration of the anesthesia in the 1 per cent. and ½ per cent. solutions was perfect for 4 or 5 days, and sensation in the ½ per cent. strength was not restored to any great extent for 10 days, and in the 1 per cent. solution sensation was not completely restored after 2 weeks. At no time was there the least pain, though the induration about the 1 per cent. and ½ per cent. solutions was yet marked at one and two weeks, respectively.

The above observations were made with the solution of the quinin in water. When physiologic salt solution was used as the solvent, the induration was little or not at all marked, but the duration of the anesthesia was much lessened. Hypotonic and hypertonic solutions also were used without notable variation.

The result of this experimentation indicated that the delayed skin union above noted was due to fibrinous exudate. This was present in 1 per cent. and the ½ per cent. solutions, but not in the ¼ per cent. solution to any notable degree. The ¼ per cent. solution seemed, then, on laboratory grounds, to be the strength most desirable for anesthesia in the class of work where speedy primary union of the skin is desirable and where duration of anesthesia beyond several hours is not required, and clinical experience seems to bear out the laboratory determinations.

Any operation ordinarily done with cocain can be done with quinin. The technic of its use is the same. As in the use of cocain, only those tissues known to be sensitive should be injected. In clean tissue the ¼ per cent. solution seems to be strong enough to produce anesthesia lasting several hours. In regions where primary union is not necessary, particularly in tissue the seat of inflammatory reaction, the stronger solutions are more satisfactory. In the opening of abscesses, for instance, and operations for anal fistulas, hemorrhoids, etc., the stronger solutions are the ones of choice. In regions in which operation is attended by hemorrhage, too, notably tonsillectomy, turbinectomy, etc., the 1 per cent. solution, or stronger (3 per cent., Brown), is the solution of choice. The stronger solution is desirable here because of the hemostatic effect exercised by the fibrinous exudate. The exudate being fibrin in the strict chemical sense, the usual natural processes of hemostasis are anticipated. The coagulum occurs, it is true, *about* and not *in* the vessels, and their occlusion, therefore, results from pressure from without. The important point, however, is that the effect lasts from 7 to 14 days, a time abundantly sufficient to allow healing by granulation to become well advanced. This is in marked contrast to the ephemeral influence of cocain and adrenalin, which act only by causing a contraction of the muscular walls of the blood vessels.

We have done the following operations, among others, under quinin anesthesia: drainage of the gall bladder, drainage of appendiceal abscesses, exploratory laparotomies, hernias, castrations, varicocele and hydrocele operations, etc., and the removal of all sorts of tumors ordinarily undertaken under cocain.

We desire particularly to emphasize the value of this anesthetic in two operations: In operations about the anus it is for us the anesthetic of choice. In both fistulas and hemorrhoids, any of the radical operations can be performed with the same thoroughness as under a general anesthetic. The advantage consists in that the duration of the anesthetic is from 7 to 10 days, which does away entirely with the after-pain ordinarily attending these operations. In tonsillectomy the results have been equally satisfactory. For this operation a large amount of the solution is injected about the tonsil between it and the faucial pillars. This forms an artificial edema about the tonsil which much facilitates its removal. An unlimited amount of solution may be used with impunity so that a satisfactory anesthesia can be easily secured. Because of its safety both tonsils may be operated on at one sitting. The absence of after-pain is as desirable here as following an operation about the anus.

As a local application about the eye we have no experience, but turbinectomies and septal spur operations have been done with a fair degree of satisfaction when the drug was used as a topical application. For local application the strength must be from 10 per cent. to 20 per cent., as correctly stated by Thibault. When the solution is injected beneath the mucosa, however, anesthesia is perfect and hemorrhage slight. It is interesting to note that Fulton[4] used quinin as a local application to the nose in hay fever.

In the bladder as a preliminary to cystoscopy the result has been very satisfactory. A solution of from 10 per cent. to 20 per cent. is used and allowed to remain from 20 to 30 minutes. The only objection to this solution is the difficulty of removing the precipitated flocculi from the bladder after the anesthesia is complete. These flocculi work no further mischief than to obscure the vision.

The chemical used is the quinin and urea hydrochlorid. For extensive operations about the rectum and throat two 2-grain tablets are dissolved in an ounce of plain sterile water. An ordinary glass hypodermic syringe is used. In cases in which relatively short anesthesia only is required and where a prompt union of the severed surfaces are desired, a 1/4 per cent. solution seems to be the solution of choice. It is unnecessary to distend the tissue. The fluid should be injected slowly under light pressure into the area to be anesthetized. The production of edema is unnecessary and should be avoided except in cases in which the edema facilitates technic (tonsillectomy, removal of encapsulated tumors). Those who have a finished technic in the use of other local anesthetics will experience no difficulty in the use of quinin.

---

[3] Noting the occurrence of induration after the injection of quinin J. J. Parsons (Practitioner, London, March, 1909) used this drug by injection into the connective tissue *lateral to the uterus* for prolapse. Our researches would seem to raise the question whether the results could be other than temporary.

[4] The Local Use of Quinin in Hay Fever, The Journal A. M. A., July 30, 1904, xliii, 325.

The advantages of this anesthetic over cocain and its congeneras are as follows:

1. Its absolute safety. One of us (Brewster) has used as much as 100 grains intravenously in 6 hours in pernicious malaria with the recovery of the patient.
2. The duration of the anesthesia. The after-pain in certain wounds is avoided.
3. The hemostatic effect.

G. W. COMBS, M.D.
INDIANAPOLIS

History.—Mr. J. L. was admitted to the City Hospital in June, 1909. He had been drinking heavily for four days, and on an evening went to a wood beside a railroad, where he lay on the ground, falling asleep and not waking until morning. He found it impossible to empty the bowel on account of an obstruction and pain. There was a beer-glass in the rectum about seven inches in circumference at the larger end, a little more than four inches in length and conically shaped. He applied for help to a physician who attempted to remove the glass, without divulsion, with forceps. The attempt failed and the glass was broken.

He was admitted to the hospital about 3 p. m. and the glass was removed about 5 p. m. The smaller end had been introduced first, and when seen at 5 p. m. was resting up about the promontory, the larger end, a segment of which had been broken out in the effort at removal just mentioned was imbedded in the hollow of the sacrum, the cutting edges being buried in the soft tissues.

Operation.—The edema and swelling, the contraction of the levators and sphincters from traumatism were such that thorough divulsion was insufficient for removal. The muscles were divided in the median line posteriorly sufficiently to effect the removal of the glass and on account of the extensive swelling and edema, and the presence of an ichorous discharge of bad odor the wound was not stitched but left to heal by granulation as in posterior proctotomy for stricture.

When the patient was discharged he had perfect control.

The shape, size and nature of the foreign body, the edema, swelling and general condition of the tissues from traumatism will be the guiding indications for the course to pursue in its removal.

If the foreign body be glass with cutting edges, much damage, which may be fatal, may follow injury to the soft tissues of the rectum or pelvis. There should be great care that a harmless body with smooth edges may not, through efforts at removal, be converted into a dangerous one with cutting edges by breaking.

It would certainly seem a rare instance in which amputation of the coccyx was necessary for the removal of a foreign body from the rectum having been introduced through the anus.

The adequate division of the muscles posteriorly and a quick removal of the object without injury is advised in lieu of prolonged efforts at removal of an object with cutting edges from which fatal wounds may result.

329 North Delaware Street.

PLACENTA PRÆVIA AND VAGINAL CESAREAN SECTION

ARTHUR STEIN, M.D.
NEW YORK

During the past few years opinions regarding the treatment of placenta prævia have undergone a radical change. Whereas until recently we were taught to overcome this dangerous complication of pregnancy or labor by a slow dilatation of the cervix followed by a Braxton-Hicks podalic version, or even by the now obsolete *accouchement forcé,* some modern obstetricians resort now to a more surgical treatment of this alarming condition.

There is still an ardent controversy as to the details of the treatment of placenta prævia in gravidity or at full term. Most of the German writers favor the method of tamponing the bleeding part by introducing the Champetier de Ribes bag, while only a few follow the American authors, who are mostly in favor of the classical Cesarean section in this condition. Some German writers (Frank, Sellheim, Krönig, v. Rosthorn, etc.) are strong advocates of the so-called extraperitoneal Cesarean section. These points, however, are of minor importance. Most authors of extended experience condemn the vaginal Cesarean section in cases of placenta prævia on account of its dangers, especially for the mother. When there is a central implantation of the placenta the vaginal route is no doubt dangerous, for by cutting into the uterine tissue the bleeding may be augmented instead of checked. In my opinion, however, there are certain cases in which the vaginal method is justifiable because it enables the obstetrician to become master of the situation quickly and safely. I have in mind those cases of lateral placenta prævia in which we are forced to rapid interference and in which we are sure beforehand that we can avoid the placental insertion.

The following case is illustrative:

History.—Patient, Mrs. B. C., aged 38, viii-para. Family history negative. Patient was always well up to the present time. She menstruated first at 16 years of age, was always irregular, every four to six weeks, and the flow was always accompanied with pain. She last menstruated on Oct. 18, 1908. She has had four normal deliveries and two instrumental ones. She can not tell what kind of instruments were used. She has had one miscarriage. The present pregnancy was uneventful up to July 6, 1909. On that day she began rather suddenly to bleed profusely and continued bleeding at brief intervals up to July 9. On July 7 the membranes ruptured. Due to the amount of blood she had lost there was occasional syncope on July 8 and 9. She was examined several times by a midwife and later by two physicians who sent her to the hospital, where I saw her first on July 9.

Examination.—At that time she was in a critical condition. Her temperature was 101.4 F., her pulse could hardly be felt, it was weak, and 128 per minute. She was in an extremely anemic condition. There was air-hunger and dizziness. She bled profusely from the vagina. As the condition was so alarming there was no time to be lost in examining the different organs, but she was put at once on the operating table and after a careful local examination it was determined to make an attempt to control the hemorrhage.

Local Examination: There was an old perineal tear of the second degree. The vulva was widely open and the vagina filled with fresh blood clots. The portio was 3 cm. long and rather rigid. One finger could be passed through the cervical canal beyond the internal os. In the cervical canal a soft, profusely bleeding mass could be felt, which was attached to the right lower part of the uterus. The anterior, posterior and left side of that portion of the uterus was perfectly free. The head of the child could be felt above the pelvic inlet. The fetal heart sounds were heard on the left side at a point midway between the umbilicus and the left anterior superior iliac spine. The frequency was 120 per minute, the action regular. At the termination of the examination some meconium was seen in the vagina.

Diagnosis.—Lateral placenta prævia, extensive hemorrhage.

Treatment.—Immediate delivery by vaginal Cesarean section. A longitudinal incision was made on the posterior wall of the cervix. The peritoneum was pushed out of the way and the posterior wall of the cervix as well as the lower posterior wall of the body of the uterus were bisected up to 3 cm. above the internal os. It seemed inadvisable to bisect the anterior wall of the cervix and uterine body as directed by Dührssen, as the condition of the patient was very poor and haste was imperative. The above-described mode of procedure, however, (Döderlein's modification of Dührssen's method) was sufficient, as it was an easy matter to introduce the whole hand into the uterus and to perform podalic version. The extraction of the child was easy with the exception of the head, which was delivered with difficulty. The child was born in a state of pallid asphyxia. In spite of the employment of all the different methods of resuscitation for about one hour I did not succeed in reviving it. The placenta was removed and the wound in the uterus closed by eight sutures of chromicized catgut.

During and after the entire operation the patient was actively stimulated.

Result.—The patient recovered rapidly. The second day after the operation her temperature was normal and the pulse was 88 per minute and full. The puerperium was uneventful in every respect. On the fifteenth day the woman left the hospital in perfect condition, though still somewhat anemic. The uterus was normally involuted, and the wound in the posterior wall of the uterus had healed primarily.

Every case of placenta prævia which has been treated by one of the newer methods should be reported in order that the general practitioner, who is most apt to deal with this dangerous complication of pregnancy or labor, may know how to treat those cases most successfully. Through reliable statistics we know that this complication occurs once in about 250 or 300 labors. The average maternal mortality is 10 per cent., whereas the fetal mortality is as high as from 70 to 80 per cent. These anything but ideal results were obtained by the routine methods of the past. The procedures were mainly: dilatation of the cervix by the metreurynter or the colpeurynter, tamponade of the vagina or even the cervix, or the performance of podalic version (Braxton Hicks), with or without perforating the placenta. *Accouchement forcé*, as I stated above, is practically obsolete. All these methods are in no way perfect, as the maternal as well as the fetal mortality is much too high. The only method that gives better results, as statistics show, is the Cesarean section, either the classical, the extraperitoneal or the vaginal. (With another method, introduced by Miller of Pittsburg, I have had no experience. In cases of central placenta prævia he ligates the uterine artery on either side through the vagina, and then, after having controlled the hemorrhage, he proceeds slowly with the delivery.)

G. T. Harrison, in a paper on "Indications for Cesarean Section in Placenta Prævia," read at the meeting of the American Gynecological Society in 1909, said that, while it is true that in the majority of cases of placenta prævia occurring in private practice the obstetric resources at our command, including manual dilatation, balloon dilatation and version are amply sufficient, there still remains a class in which the performance of Cesarean section, whether vaginal or classical, might well merit serious consideration. The cases referred to are those in which dangerous hemorrhages occur, while at the same time the cervix is preserved in its entire length. The classical Cesarean section should be reserved for cases in which the vaginal procedure is excluded as, for example, contracted pelvis.

Bumm, who probably has had the largest experience with vaginal Cesarean section in placenta prævia, is an ardent advocate of this method. As far back as 1905 he said that during the operation he has constantly the feeling of full security against loss of blood and he believes that the vaginal hysterotomy in women who have already lost much blood at the beginning of the dilatation may be effective in saving life. At all events, it is superior to the abdominal Cesarean section in the smallness of the wound and to all dilatation procedures in the certainty of arrest of hemorrhage.

Baisch also holds the same opinion, which he bases on 10 cases of placenta prævia. There are a few more successful cases reported by Dührssen (the originator of the vaginal section) and by Everke.

In my case I had to do a quick and at the same time safe operation. Classical Cesarean section was out of the question, as the patient had a temperature of 101.4° F. and had been examined vaginally several times before I saw her. The extraperitoneal operation was also excluded in this particular case, as I had to choose the quickest way to deliver the patient and this is, by all means, the vaginal route. It is surprising—as I previously stated in another publication[1]—how easily this operation can be performed and how insignificant is the hemorrhage from the wound. With few exceptions all the writers on this subject admit this. In my case, also, I was astonished to see that the patient lost no blood to speak of. The whole operation was performed in eight minutes, as I decided to do only a posterior incision to save valuable time. I am aware that the result is by no means ideal so far as the baby is concerned, as we could not revive it after an hour's effort. I succeeded, however, in saving the mother's life.

In conclusion, I would suggest that in similar cases this mode of procedure be used, particularly as the general practitioner who has had some surgical experience and who has at least one competent assistant at hand may be able to perform the operation even under unfavorable conditions. This operation enables one to open the uterus enough to permit delivery along the normal passages, without loss of time, in a clean-cut surgical way, and at any moment during pregnancy or labor.

1 West Eighty-fifth Street.

A VISCERA SPOON

DAVID O'SHEA, M.D.

CHICAGO

The instrument which I have devised and which is here illustrated is intended to protect the viscera during operations. It is made of heavy block tin, is about eight inches in length and consists of two spoons of different sizes, having their concavities facing in opposite directions and connected by an isthmus that runs obliquely. The larger spoon is four inches long and one-half inch in depth, the smaller one being about half that size. The instrument is now in use at Mercy Hospital, Chicago, and has proved a practical device.

A CASE OF DIVERTICULUM AT THE PYLORUS *

ALLEN A. JONES, M.D.
Adjunct Professor of Medicine, University of Buffalo
BUFFALO

History.—The case I have to report is that of a young man, aged 21, a college student in Toronto, who came to see me first on Sept. 22, 1894. His father and mother were living, the latter being of extremely nervous temperament and having had recurrent stomach trouble for some years. At the age of 18, the patient had experienced attacks of severe pain in the stomach after meals and when he saw me first, he complained of pain about two inches above the umbilicus, radiating a little to the left. There was no history of vomiting of blood. The thoracic organs were normal. He had a slight astigmatism with, at times, a trifling headache. He was cheerful and slept well. His appetite was very good and craving at times. His pain between meals was relieved by rest and milk and cream, egg or ice-cream. On examining his stomach, free hydrochloric acid was found present and after considerable retching there came through the stomach-tube a small quantity of blood-stained water and a fragment of mucous membrane, 1½ cm. long by 1 cm. wide which was soft and friable and studded with dark extravasations, such as is sometimes found with gastric erosion or torn off by rough handling or suction of the stomach-tube. He was constipated; his urine was normal; he gave no specific history. There was no food stagnation. His symptoms abated and he improved on alkaline gastric sedatives with nux vomica, physostigma and stillingia. He came to see me again in 1905, four months after his appendix had been removed. He then complained of pain in his stomach which sometimes induced vomiting. The total acidity of his gastric contents was 60; free hydrochloric acid, 10 per cent. Acid salts, 12; combined chlorids, 20; biuret, present; rennet, present; erythrodextrin, +. Microscopic examination, negative. His stomach was empty before breakfast. Two days later, four and one-half hours after Riegel's test meal, there was some mucus present; a total acidity of 30; free hydrochloric acid, 0.09 per cent. He returned home and on rest, fresh air and tonics, improved very much. In September, 1906, he came back complaining of vomiting and gastric pain, flatulency and loss of weight. Again in May, 1908, shortly after returning from England, he came with gastric symptoms similar to those he had presented in the past.

Operation.—Dr. Cornell, of Brockville, Ontario, being present and concurring, on Nov. 25, 1908, Dr. Carlton C. Frederick operated and reports the following: There were adhesions found about 2 cm. in diameter, about 4 cm. from the pylorus on the anterior stomach wall, between it and the transverse colon and gastrocolic omentum. The adhesions were broken up and the denuded surface closed over by fresh peritoneum. Between this point of adhesion and the pylorus, just inside the pyloric ring on the stomach side, was a diverticulum consisting, apparently, of serous and mucus membranes only. To remove this diverticulum necessitated doing a modified Finney operation. The modification consisted in bringing the duodenum farther forward than in the ordinary operation for pyloroplasty, and after the first line of sutures, which are usually passed through the peritoneum, instead of making the horseshoe-shaped incision the diverticulum was excised, and from its upper curve the balance of the necessary horseshoe-shaped incision was carried beyond the pylorus down to a sufficient distance in the duodenum. After the operation was completed, the duodenum lay in front of the anterior wall of the pyloric end of the stomach instead of in the usual position after a Finney operation, along the subpyloric curve.

Postoperative History.—Since the operation the patient has gradually improved and now weighs 136 pounds. When he left the hospital his weight was 104. He makes no complaint of his stomach and says he feels better than he ever did.

The interesting points about this case are, first, that it is probable that the patient had a gastric ulcer at the age of 18; that this ulcer destroyed the muscular coat of the stomach, and that in healing this coat was not restored, but the pyloric wall in that region consisted chiefly of the serous and mucous coats, the latter having undergone regeneration. This thin and weak portion of the pylorus gradually stretched and formed a diverticulum. As a rule, gastric ulcer at or near the pylorus gives rise to cicatricial contraction, with more or less stenosis following, but in this instance such was not the case.

The second point of interest simply consists in the illustration that this case affords of the fact that cases of long-standing gastric complaint often show organic disease of the stomach or adnexæ. The examination of the gastric contents showed a variable chemistry in this case, and revealed also an unstable motor condition.

During the years between 1893 and 1908 the patient was a gastric semi-invalid, and his tolerance of the organic change in and near his pylorus was insufficient to maintain him in vigorous resistance and health, probably owing to his temperament and a delicate physique. His gastric symptoms consisted usually of a combination often present in gastric neuroses, which emphasizes once more the clinical fact that some or all of the symptoms of the gastric neuroses may exist with structural alteration and that operation, which should have been done earlier in this case, affords the only relief or cure for such structural change.

In the causation of this patient's symptoms, the perigastric adhesions may have been chiefly instrumental, although it is impossible to estimate the degree of disturbance caused by the deformity of the pylorus, the caliber of which was ample.

436 Franklin Street.

ABSTRACT OF DISCUSSION

Dr. Charles G. Stockton, Buffalo: This seems to me to be a very unusual case. So far as I know, this is the only instance in which a diverticulum has appeared in that region and the only instance that I know of what undoubtedly was a gastric ulcer so destroying the wall of the stomach as to result in a diverticulum. Those two facts appeared undoubtedly in the case reported by Dr. Jones.

Dr. Allen A. Jones, Buffalo: This diverticulum was two and a half centimeters (2.5 cm.) in depth. It had pressed on and dilated the pyloric ring, really involving a part of it. It also dilated the duodenum two centimeters (2 cm.) beyond the ring. With this pressure in the antrum pylori one can readily understand how it would become a condition that would be a symptom producer. It is impossible for us to say now how much perigastric adhesions had to do with the causation of the symptoms, or how much the deformed condition of the pylorus was to blame.

THE USE OF BISMUTH GAUZE IN GYNECOLOGIC WORK

SOLOMON WIENER, M.D.
Assistant Adjunct Gynecologist, Mount Sinai Hospital
NEW YORK

Some substitute for iodoform gauze has long been needed in vaginal work. One of the most important functions of gauze impregnated with iodoform, or one of its derivatives, is to deodorize the accumulating secretions, which become very foul under the action of the ever-present saprophytic organisms. It is frequently necessary to leave gauze in the uterine cavity and vagina for from two to five days, and such gauze, if unmedicated, soon becomes exceedingly foul-smelling and offensive alike to the patient and to those around her. In addition, the presence of decomposing material has a most unfavorable influence on the smooth healing of wounds. Iodoform gauze, unless it be very strong, is little better than plain gauze in this respect. It may remain fresh and sweet for forty-eight hours, but if left *in situ* any longer it becomes very fetid, especially in the presence of the increased secretion stimulated by the irritating presence of sutures in the vagina. The odor of iodoform itself is objectionable to many people. In addition, one is never certain that, given a raw area and a duly susceptible patient, symptoms of iodoform poisoning will not supervene. Moreover, the iodoform gauze as put up in sealed tubes for use in private practice is quite expensive.

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

For the past four months, in the gynecologic service of Dr. Florian Krug at Mount Sinai Hospital, we have been using gauze impregnated with subnitrate of bismuth, with highly satisfactory results. It is prepared by taking 2 ounces of bismuth subnitrate, 2 ounces of glycerin, and 1 quart of water. The bismuth and glycerin are very thoroughly mixed, warm water is gradually added and the mixture is continually stirred so as to make a fine emulsion.

A portion containing about 21 yards of gauze is passed slowly through the emulsion three times so that it becomes thoroughly soaked, and is then wrung out. After the gauze is dried it is cut into strips of desired size, loosely packed, and sterilized by steam at seven or eight pounds' pressure for thirty minutes.

The above strength has proved sufficient for our purposes; it could be considerably increased without harmful effects should the occasion warrant it.

The gauze so prepared is snowy white in color, odorless, soft and smooth. There are no grains of powder macroscopically visible on it. From plain unmedicated gauze it differs only in its intense white color and in being smoother and softer to the touch. From iodoform gauze it differs in being odorless, absolutely non-toxic in the quantity used in any one case, much softer, less irritating, and less expensive. (Bismuth subnitrate is from 30 to 40 per cent. cheaper than iodoform.) Finally, it is far more efficient in its action.

I have used it in a great many cases, and have found that after incomplete abortions, curettages, plastic operations on the cervix and vagina, and aseptic vaginal celiotomies, it can be left in the vagina for a week, if desirable, and on removal it is still perfectly sweet and odorless.

The mucosa is pale and unirritated, and there is none of the stench so distressing to the patient and all concerned. The advantages are obvious.

It should be noted that the gauze has not the power of deodorizing foul-smelling pus. When, for instance, a pelvic abscess containing foul-smelling pus is opened and drained by a postvaginal section, the gauze has little or no power to mitigate the fetor. In aseptic cases we have, after extended trial, found it almost ideal and can heartily recommend its use to others.

Its uses in other fields of work will readily suggest themselves.

67 West Eighty-ninth Street.

Cow's Milk.—Cow's milk is the only food supply apart from mother's milk available in this country, from a practical standpoint, for the nourishment of infants under 1 year of age. It forms, besides, a large part of the dietary of older children and of many adults. It is consequently of the utmost importance, in view of its perishability, that it should only be used as a food under conditions which will insure its wholesomeness.—J. W. Schereschewsky, in *Annals of Medical Practice.*

SARCOMA OF THE TONSIL

REPORT OF A CASE, WITH REMARKS ON THE TECHNIC OF THE OPERATION *

JOHN E. SUMMERS, M.D.
OMAHA

The relative infrequency of sarcoma of the tonsil and the apparent hopelessness of the patient prompt me to write this paper.

History.—E. M., Wood River, Neb., Dane, aged 48, farmer, single. Family history negative; no history of injury; no previous history of sickness that would have any bearing on present condition. The patient entered Omaha General Hospital, Jan. 6, 1908, with the following story: In June or July, 1907, he noticed a slight "fulness" or "swelling" of the left tonsil; not enough to trouble him particularly, and not enough to have remembered, had not subsequent developments caused him to recall early symptoms. This condition continued until the early part of November, 1907, the "fulness" and "swelling" gradually but slowly becoming more pronounced. From November until the time of presentation for assistance, the swelling had enlarged quite rapidly, and worried the patient a great deal. At no time had he detected enlargement of any of the cervical lymph nodes, and at no time did he suffer from pain.

Examination.—The patient was pale and had an anxious expression. Examination of the throat showed an enlargement of the left tonsil to such extent that it almost filled up the pharynx, there being only a narrow chink between the right tonsil, the right pillars of the fauces, and the border of the new growth. There was an ulcerated necrotic area of the tumor, about the size of a quarter, which had ulcerated through the soft palate to the left of the median line. The jaws could not be widely separated; the tumor could be distinguished below the angle of the jaw, and a few enlarged lymph nodes could be felt below the tonsil in the carotid triangle. The man had been refused operation by several surgeons, as the growth was considered too advanced to make the hazard of operation justifiable.

First Operation.—After the usual preliminary antiseptic treatment of the mouth and throat, the patient was operated on, Jan. 9, 1908. Briefly, the technic employed was: (1) ether anesthesia, ligation of the left external carotid artery, and (2) a prophylactic laryngeotracheotomy (division of the cricoid cartilage and the upper three tracheal rings). The cricoid cut being held wide open, gauze was packed into the wound above the tube, to prevent leakage of blood into the bronchi. The anesthesia was continued by having a piece of cotton clamped in a forceps kept moist with chloroform and held over the opening in the tracheal cannula—my usual technic whenever I am doing extensive bloody operations about the throat, as, for instance, for malignant disease of the tongue and floor of the mouth and larynx. With the head and shoulders elevated, the cheek was split from the angle of the mouth to the angle of the jaw, joining a curved incision around the angle of the jaw. The jaw was divided. The wound was widely retracted and there was no difficulty in excising the soft palate and in enucleating the tumor, which was distinctly encapsulated. The wound was closed in inverse order to the method of making it, the mouth being shut off from the wound cavity by suturing in such a way as practically to limit the drainage through the external wound.

Convalescence was uninterrupted, but slow because of the man's run-down condition. At the end of six weeks a Crile block operation was carried out; union was *per primam* and the man returned home and renewed his occupation of a farmer.

Second and Third Operations.—Feb. 6, 1909, the patient returned with a recurrence at the site of the tonsil. This was removed through an external incision without opening the mouth, and again, April 27, the same kind of recurrence and the same kind of a removal.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

The man is now in good condition. He has no pain and has a good appetite. Had he not been operated on in January, 1908, he would have been dead more than one year ago. He is not cured, but even now the outlook is not hopeless.

Pathologic Report.—Dr. Paul G. Woolley describes the tissue from the tonsil, removed at operation, as follows: "Celloidin shows that the tissue is composed of a very cellular growth made up of polymorphous cells, thin-walled blood vessels and vascular spaces, and supplied with a well formed intercellular reticulum. One portion of the tumor, that forming an ovoid nodule, is somewhat edematous, and is more richly supplied with vessels than is the deeper layer, which is composed of a more compact mass of cells. Running in all directions in the former portion are strands or columns of spindle-cells, between which lie the polyhedral cells that immediately surround the vascular spaces in such a way as to suggest a perithelial origin. This is, however, I believe, merely a suggestion, for in the more cellular parts there is no such indication of vascular origin. The tumor is a sarcoma composed of polymorphous cells."

My special object in directing attention to the surgical technic in attacking tumors of the throat is to emphasize the importance of two points, viz., early diagnosis, and the thorough, radical removal of the growth together with the lymph nodes, whether apparently healthy or diseased. I advocate most strongly, for the throat and neck, the kind of operative attack which has added so many years to the lives of sufferers from cancer of the breast. Prior to the general adoption of the Halsted operation for cancer of the breast, almost every patient suffered a recurrence and died. The percentage of cures following operation for malignant disease of the tonsil is necessarily lower than in cancer of the breast because of the more early lymphatic involvement; yet statistics in this operation will improve when an adoption of the "block" technic of Crile is more general. Crile, in speaking of this, makes a comparison of the results in his own practice in a series of ninety-six cases of malignant disease of the type under consideration, i. e., cancer of the neck and throat, the operation being done under usual methods, giving a three-year limit; over 28 per cent. of the patients remained free from recurrence.

In a series of thirty-six operations under the "block" system, 52 per cent. of the patients are living and free from recurrence.

In considering the mortality of the operation for removal of malignant growths of the tonsil, we must first remember that the early diagnosis, when the neoplasm is confined to the tonsil itself and has not spread to contiguous parts (as the base of the tongue, palate, pillars of the fauces, upper part of the larynx, the pharynx) is the key to the prognosis. In epithelioma this spreading is very rapid, and in sarcoma of the small-celled variety almost equally so. In the other sarcomata, there is little disposition to spread early; in fact, the growth may for some months be encapsulated, and it is in this variety that glandular involvement is also much later manifest.

Mr. Butlin gives the histories of fifty-four patients' cases on whom operations of various severity were performed.

Died of the operation	14
Alive or dead with recurrence (in mouth or glands)	20
Died of cancer elsewhere	3
Well from one to three years	8
Well more than three years	9
Total	54

These statistics are most encouraging, as all previous work had been extremely discouraging, nearly all cases having proved fatal as in the earlier operative treatment of cancer of the breast. Now, if we can add the additional improved technic of the "block" operation applied to malignant disease of the tonsil, diagnosed early, the outlook will be still more encouraging. It is only essential to mention the lines of attack.

1. Through the mouth.
2. By incision in the neck—lateral pharyngotomy.
3. Combined operations, through the mouth by splitting the cheek, and lateral pharyngotomy.
4. Median or trans-hyoid pharyngotomy. Lateral pharyngotomy. Division or resection of the jaw. Ligation external carotid. Tracheotomy. Combined operation or removal of the glands two weeks to two months later.

I agree with Mr. Childe, that the tonsil should be dealt with first, after ligation of the external carotid. If the reverse procedure is carried out and the "block" operation is performed on the lymph nodes first, the resultant scars may obliterate the anatomic guides to such a degree as to render exceedingly difficult the attack on the tonsil by means of a pharyngotomy.

Fifteenth and Dodge Streets.

ABSTRACT OF DISCUSSION

Dr. Miles F. Porter, Fort Wayne, Ind.: I have had one unusual experience in dealing with malignant disease of the tonsil, involving the fauces. The case was apparently hopeless, but the individual is now symptomatically cured as a result of the combined use of the toxins and the injection of boiling water.

This shows that there are patients who are beyond hope of cure by radical operation who can be relieved and occasionally cured by the use of boiling water and the toxins.

Dr. H. S. Wieder, Philadelphia: Dr. Summers' paper brought out two points, especially with reference to sarcoma of the tonsil.

First, in sarcoma of the tonsil, not following the usual rule of sarcoma, there is almost invariably involvement of the lymph glands below the jaw and down the side of the neck. That is in opposition to the usual course of sarcoma, which usually travels by way of the vascular system. The tonsil being a part of the lymph system and being rich in lymphatics which empty into the lymph vessels of the neck, early metastasis to the neck takes place.

The second point I refer to is the fact that there are early recurences in sarcoma. If the recurrence does not take place within a year or two, one can feel a comparative amount of safety, although one case has been reported in which recurrence took place as late as nine years after operation; this is the exception, however. In carcinoma one cannot feel safe, even after the lapse of three years.

Dr. J. E. Summers, Jr., Omaha: Dr. Wood had two cases, but they were of a different type from mine; in fact, I could not quite see some of his points; therefore, I was unable to use his work. Dr. Warren read a paper at the International Congress of Surgery, at Brussels, in which he collated all the cases of cancer of the floor of the mouth, tongue, tonsil, etc., that occurred in the Massachusetts General Hospital during a number of years. There were four cases of sarcoma of the tonsil, and all the patients died. The point I wanted particularly to bring out was that we must make an early diagnosis and operate promptly.

Books on surgery and laryngology do not say how to make the attack. To prevent a recurrence of the growth the surgeon must do just as he would in cancer elsewhere, e. g., cut out all the diseased tissue. Formerly we believed that cancer was a constitutional disease. Why? Because surgeons removed the breast and the tumor recurred. Therefore, it was a constitutional matter. Remove the local growth carefully; go away outside of it. Do a Crile block operation on the lymph nodes in the neck. In a case like mine, considering how much has been accomplished by this method, I think that it is good practice.

Therapeutics

APPENDICITIS

The medical treatment of this inflammation is ever a subject for discussion, and there is an ever-varying opinion as to the best management before operation and when operation is inadvisable. In a series of essays on the subject which appeared in the *New York Medical Journal* from May 29 to June 19, 1909, inclusive, various treatments, and some diametrically opposed treatments, are described.

The consensus of opinion of the best management of appendicitis, at least the best composite opinion, as judged by the editor of this department, may be summed up under various headings as follows:

1. The most important of the treatments of this condition is rest, and that absolute. In most instances even arising from the bed for evacuation of the bowels, or for urination, should be prohibited. The position of the patient should be that in which he experiences the least pain.

2. The next important treatment is catharsis. There is a wide variance of opinion as to the advisability, value, or necessity of purging. If the patient is seen early in the disease, it seems that there can be but one opinion as to the advisability of removing feces, possibly retained fecal masses, and all sources of bowel infection, from the intestines in this abdominal inflammation, and in a patient who may be subjected to the necessity of etherization, abdominal operation, and subsequent intestinal rest. If the patient has been previously purged, or if diarrhea has occurred (although diarrhea may not remove all fecal matters), or if the patient is first seen after several days of the disease, the advisability of purgatives may be more carefully considered, and it may be deemed inadvisable to use them.

The cathartic selected should generally be a saline or castor oil. The saline may be administered in divided doses, or in one or two large doses, and the one selected should depend on the condition of the stomach; the pleasantest, if there is nausea and vomiting; Epsom salts, if nausea is not present. Castor oil may be given in elastic capsules, or with oil of wintergreen, saccharin, or black coffee, or in some other pleasant manner. The dose should be sufficient. Any excessive action of the bowels should be stopped by the administration of a small dose of morphin, and the intestines thus made empty and at rest, the condition desired in appendicitis.

3. As so well pointed out by Dr. George A. Graham, of Kansas City, Mo. (*New York Medical Journal,* May 29, 1909), many an apparently first-stage appendicitis is really an irritation and inflammation of the cecum, due to the stasis of food débris and fecal matters in this blind sac. Such a condition of the cecum will sooner or later cause appendicitis, if it is not already present. In either case, this stagnant, irritating, foreign matter, which may contain various fruit seeds or other indigestible material, should be removed by high colon washings, the patient lying with the pelvis elevated and on his right side. Even after previous purgation it is sometimes astonishing to find what substances such high enemas will bring away. The water should be used warm, and if deemed advisable warm olive oil injections may also be used. Such washings should be repeated until the water comes away clear. These enemas may cause some increased pain in the appendix region, but the subsequent improvement of the patient is often so rapid and so satisfactory that the treatment is justifiable and prophylactic.

4. While there seems to be a difference of opinion in regard to the application of the ice bag over the right lower quadrant of the abdomen in appendicitis, there is no doubt of its generally very great value. The bag of cracked ice should not be too full or too heavy, and the region of its application should be limited to the region of the appendix. In other words, the liver and diaphragm region should be protected from the action of the cold, and the same is true of the pubic region, by towels or flannel properly applied. While the cold applications may tend to cause contraction of the abdominal muscles, its action is soon sedative, and pain often ceases from this physical therapy alone. If the inflammation is not aborted in twenty-four or thirty-six hours, the time for the use of ice is past, and warm moist applications are then advisable to cause muscle relaxation and less tension over the inflamed region.

5. While morphin or codein are considered contraindicated by many surgeons, as tending to mask the pain and therefore the extent to which the inflammation has extended, there is no question that morphin, properly administered, in doses sufficient to stupefy the patient, are many times not only needed to prevent shock from the intestinal pain, but also to give not only rest and sleep, but especially intestinal rest, and by these actions it can aid in aborting the attack. As above stated, it seems unwise to give patients morphin when the intestines are loaded with fecal matters, but after such matters have been expelled, and there are no toxins or fermentative products in the gastrointestinal canal, the sedative action of morphin can do nothing but good. Pain alone is but one symptom in determining whether or not operation is necessary, and generally enough other symptoms are present to decide such a procedure as to preclude the necessity of allowing the patient to suffer pain. Also, pain long continued increases the probability of shock occurring after operation. Let it not be misunderstood that the dose of morphin should be large. It is astonishing at times how little is needed to quiet peristalsis and therefore to quiet pain. Sometimes 1/10 of a grain is all that is needed, best given hypodermatically. More often 1/8 of a grain is required, but it need not be repeated for hours; 1/4 of a grain at one time should not be administered in appendicitis, as it is not necessary. In a few hours the patient has come out of the sedative effect of the morphin, and if the pain is worse than before, or as bad, it is easily noted. If the pain is much less, the morphin has aided in causing such improvement.

6. There is a great variation in the opinion of physicians and surgeons as to whether food should be given by the stomach when it is attempted to abort an appendicitis. The advice varies from nothing at all by the stomach, not even water, to the administration of plenty of milk. The composite advice would seem to be that the patient should receive no real food for twenty-four hours, but water should be allowed, and best hot, or perhaps hot tea or hot bouillon. Hot drinks do not start peristalsis, which has been named as the objection to all foods or drinks by the stomach. If morphin has been administered, of course, it would inhibit peristalsis, and there is more necessity for water, or other bland liquid, to be administered to prevent nausea from the morphin which is excreted into the stomach.

7. It seems advisable to operate if, in from twenty-four to thirty-six hours:

(a) Pain has increased.

(b) There is much increased resistance in the right iliac region.

(c) The temperature is higher and the diagnosis is clear.

(d) The pulse is high, even if the temperature is low, especially if the facial expression is anxious—in other words, the peritoneal expression.

(e) If the leucocyte count is 18,000, or over, and another count in six hours shows an increase. The absence of leucocytosis, or a low white blood count, does not preclude the necessity of immediate operation. The conditions of fulminating appendicitis are almost like conditions of shock, and leucocytosis may not have had time or opportunity to develop.

(f) If there is a sudden subsidence of pain, and other symptoms show that the inflammation has not aborted, gangrene may be present, and the operation should be immediate.

If under any of the above-named conditions operation is refused, or if the general condition of the patient, or the presence of serious chronic disease, makes operation inadvisable, the treatment advised below should be inaugurated.

8. Operation may be deferred, if the above imperative symptoms are not present, even if the local induration and mass increases in size.

9. On the second day of the inflammation the diet may consist of two raw eggs, coffee or tea, meat juice, and plenty of water.

10. If the progress of the inflammation is toward recovery, on the third day more solid but easily digested food, as milk toast, oatmeal gruel, and poached eggs may be allowed.

11. If the patient does not improve and the inflammation is still active, the third day diet should be the same as that described under 9, i. e., the second day diet.

12. If a tumor mass has formed in the appendix region, tension of the abdominal walls may be relieved with flaxseed poultices, or other hot moist compresses.

13. If perforation seems likely and peritonitis imminent, and an operation is not allowed or not advisable:

(a) Put the patient in 45° upright position with the thighs well supported by pillows, as this position tends to cause drainage to the lower part of the abdomen and pelvic peritoneum, where less absorption is likely to take place than when drainage is toward the upper abdomen.

(b) Frequent high colon injections of physiologic saline should be given, and the colon not only gently washed, but the saline solution should remain in the colon to promote its absorption, as full blood vessels will prevent absorption from the seat of infection.

14. If signs of peritonitis are present:

(a) Continuous saline infusions into the colon by the Murphy method should be given. This is well described by Dr. John B. Murphy, of Chicago, in *Surgery, Gynecology and Obstetrics,* June, 1908. He believes that his method of administering saline solution, which he terms "proctoclysis," is such a factor in diminishing intoxication and in saving life that his description of the method should be given in his own words, viz.: "The fluid should be administered through a fountain syringe to which is attached a ⅜-inch rubber hose fitted with a hard rubber or glass vaginal douche tip with multiple openings. This tube should be flexed almost to right angles three inches from its tip. A straight tube must not be used, as the tip produces pressure on the posterior wall of the rectum when the patient is in the upright or Fowler position. The tube is inserted into the rectum to the flexion angle and secured in place by adhesive strips binding it to the thigh so that it can not come out; the rubber tube is passed under the bedding to the head or foot of the bed to which the fountain is attached. *It should be suspended from six to fourteen* inches above the level of the buttocks and raised or lowered to just overbalance hydrostatically the intra-abdominal pressure, i. e., it must be just high enough to require from forty to sixty minutes for 1½ pints to flow in, the usual quantity given every two hours. The fluid must be controlled by gravity alone. and never by a forceps or constriction on the tube, so that when the patient endeavors to void flatus, or strain, the fluid will rapidly flow back into the can; otherwise it will be discharged into the bed. It is this ease of flow to and from the bowel that insures against over-distention and expulsion on to the linen. The fountain had better be a glass or graded can so that the flow can be estimated. The temperature of the water in the fountain can be maintained at 100° by encasement in hot water bags. The fountain is refilled every two hours with from 1½ to 2 *pints of fluid.* The tube should not be removed from the rectum for two or three days." Under this treatment the blood pressure is restored to normal, thirst is quieted, and septic products are more readily excreted.

(b) Morphin should be administered in sufficient quantity to stop peristalsis.

(c) The daily diet should consist of several raw eggs, the juice expressed from a pound of chopped steak, and perhaps one or two cups of malted milk.

(d) Whiskey, or brandy, should be given in small amounts. Five drops of the tincture of strophanthus, or ten drops of the tincture of digitalis, may be given three or four times in twenty-four hours to aid the circulation in fighting the depression from the infection. After several days of high fever, however, such cardiac tonics as strophanthus and digitalis should ordinarily not be given.

(e) Strychnin should be reserved as long as possible, and can be given at such a time as digitalis and strophanthus are contraindicated, and its best action is produced by hypodermatic administration; 1/30 of a grain every six hours thus administered is as large a dose as should be used, and the frequency that should be used, except in an emergency. In other words, too much strychnin should not be given.

15. After complete recovery from a severe attack of appendicitis a child surely, and an adult generally, should be operated on; in other words, an operation during the interim, and one from which the mortality is perhaps less than 1 per cent.

16. If the patient is not seen until an abscess has formed, or until peritonitis is present, while the results of operation are doubtful, the danger of not operating is greater; hence operation should be advised.

Serotherapy of Metrorrhagia.—E. Nuñez states in the *Semana Medica*, June 10, that the success of serum injections in hemophilia suggested the possibility of influencing excessive menstrual hemorrhage by this means. Metrorrhagia of ten or fifteen days' duration seems to be common in his country, Argentina, in virgins or nulliparæ, with no discoverable cause for the excessive hemorrhage. Repose, a milk diet and ergot or other styptics do not seem to influence the hemorrhagic tendency in these cases, but benefit followed injection of 10 or 20 c.c. of antistreptococcus serum each month, for two or three months, the menstrual flow keeping thereafter within normal bounds. He cites a number of cases in detail. In one young woman the excessive hemorrhage ceased within twenty-four hours of the injection each time until normal conditions seemed to be permanently restored. The effect was equally marked in two multiparæ of 41 and 47, but no benefit was apparent in cancer cases.

SATURDAY, OCTOBER 23, 1909

THE FREQUENCY OF TUBERCULOSIS IN MAN

A few years ago Naegeli aroused widespread interest by reporting that a careful examination of a large number of bodies had demonstrated the presence of evidences of tuberculosis in over 90 per cent. The findings attracted wide attention because they were so startling and because they justified the old axiom of "every one has a little tuberculosis," and so Naegeli's figures have been widely quoted and almost universally accepted. For the most part pathologists supported Naegeli's contention, for their experience in autopsy work had shown them that few adult bodies were free from calcified peribronchial glands, calcified nodules in the lungs, pleural scars and apical adhesions, which lesions are all suspicious, although not positive, evidence of healed tuberculous processes. General impressions are one thing and careful analysis of evidence is another, however, and as regards this very important matter of the tuberculosis morbidity, the former have been much more abundant than the latter. Burkhardt found in the material investigated at Dresden about the same high proportion of tuberculosis as Naegeli had found in Zurich, but by Lubarsch the occurrence of tuberculous lesion was placed at but 70 per cent., and Necker's figures are about the same as Lubarsch's.

The latest contribution to this question was furnished by Beitzke,[1] who had examined 1,100 bodies at the *Charité*, in Berlin, with particular reference to the occurrence of healed and active tuberculosis, and his results are somewhat lower even than those of Lubarsch and Necker. In children under 15 years of age, as is to be expected, tuberculosis is less common than in adults, involving but 27.3 per cent. of 198 children, and in about half of these it was the cause of death. In 703 bodies of persons over 15 years of age active tuberculous lesions, calcified nodules, and positively tuberculous but healed lesions were found in 409, or 58.2 per cent.

Beitzke believes that Naegeli's statement, that almost every adult is tuberculous, should be changed to read thus: "In the autopsy material of the hospitals of certain large cities nearly every adult body is tuberculous." He believes that the high figures obtained by Naegeli and Burkhardt are to be ascribed, at least in part, to a high tuberculosis rate in the cities in which their investigations have been made, and especially to the class of patients served by large charity hospitals, in whom tuberculosis is much more common than in the rest of the population of the country at large. Therefore, Beitzke believes that we are much more nearly correct if we assume that only about one-half of all persons in all states of society suffer from a demonstrable tuberculous lesion during their lives.

It would seem, however, that the chief reason for the discrepancy in these several sets of statistics lies in the interpretation put on certain pulmonary lesions by different pathologists. All agree that encapsulated caseous areas in lungs or lymph glands are certainly tuberculous, and that calcified nodules in the same locations are nearly always, but not invariably, the sequel of healed tuberculosis. There are found, however, certain lesions of more debatable origin, including the common puckered scars and pleural adhesions at the apex, and the minute fibrous nodules of two or three millimeters diameter in the lung and pleura. Naegeli and many others believe that such lesions represent healed tuberculosis and include them in their statistics as such. Others, among whom is Beitzke, do not believe that these areas are always of tuberculous origin, and leave them out of consideration. If Beitzke had included these lesions in his tables, or if Naegeli had left them out of his statistics, the two pathologists would have been in reasonably close agreement, and the same thing may be said of the rest of the statistics. It is evident, therefore, that we cannot be sure whether nearly all persons have tuberculosis at some time, as Naegeli maintains, or whether Beitzke is more nearly correct in implicating but half the population, until we know how large a proportion of all the pleural and pulmonary scars represent healed tuberculosis. That is a difficult problem which we must ask the pathologic anatomists to work out. In any case it is certain that the estimate of 58 per cent. of healed and active tuberculosis in the bodies of adults represents a minimum figure, and that it is possible that the higher estimates of from 70 to 95 per cent. may prove to be correct.

THE EFFECT OF CAFFEIN ON THE TOXICITY OF ACETANILID AND ANTIPYRIN

The origin of the prevalent custom of adding caffein to prescriptions containing acetanilid, antipyrin, and acetphenetidin has not been satisfactorily explained. For two or three decades before the introduction of the "coal-tar" antipyretics, caffein was in somewhat extensive use as a remedy in neuralgic and other headaches, and it may be that this use suggested its combination with the newer antipyretics. Whether or not this was the case, there can be little doubt that at present the motive which usually leads physicians to add caffein to prescriptions containing these "coal-tar" products is a belief that it will counteract the depressing effects of the latter—a belief that has been long and assiduously fostered by the manufacturers of headache nostrums. The clinical literature on this subject contains no evidence that caffein actually has this effect; the belief is apparently based on the pharmacologic action of caffein as a cardiac and respiratory "stimulant" as opposed to that of the antipyretics which are considered to be "depressants." The question evidently is primarily a pharmacologic one and its solution is to be sought in careful experiments on lower animals; only thus was the true pharmacologic action of digitalis, for example, discovered.

---

[1] Berl. klin. Wchnschr., 1909, xlvi, 388.

Hale[1] has recently published an investigation of this character; his results will doubtless be a surprise to many physicians. Briefly stated, he finds that caffein has little or no activity in counteracting the deleterious effects of either acetanilid or antipyrin on the heart; it does have some activity in preventing the slowing of the heart caused by these drugs, but it has practically no effect, or if any an injurious one, on the contractile power of the heart. On the intact animal, caffein is not only *not an antagonist to acetanilid and antipyrin*, but it actually increases their toxicity, so that animals die from smaller doses of these when small amounts of caffein are given simultaneously than when the acetanilid or antipyrin is given alone.

These results do not necessarily prove that the combination of caffein with these antipyretics may not at times be advantageous; as was pointed out above, caffein alone has considerable value in relieving certain forms of headache. But they do show that physicians should not trust to caffein to counteract the injurious effects of these drugs and that the doses of the latter should be lessened when prescribed with caffein; many physicians are under the impression that larger doses may be prescribed if caffein is added, and the dose of the Pulvis Acetanilidi Compositus, U. S. P., is larger (as regards acetanilid) than that of acetanilid itself.

Hale's paper contains many other points of interest. Thus he finds that the alkaloids of the morphin group also increase the toxic effects of acetanilid, while mixtures containing salicylic acid and the bromids seemed not to alter its poisonous effects in any way. Sodium bicarbonate lessened the toxicity of acetanilid both on the heart and on the intact animal; it had a similar action toward antipyrin so far as the heart was concerned, but not as regards the intact animal.

The results of these experiments bring to the front once more the baneful effect that the proprietary nostrum business has had on pharmacology. The medical profession has accepted without question the proposition iterated and reiterated by manufacturers of headache "cures" that caffein renders acetanilid "safe." Scientific work, unhampered by any commercial considerations, determines that the direct opposite is actually the fact. Such work as this of Hale's will do much toward placing pharmacology on a firmer basis and restoring that confidence in the materia medica which it deserves.

THE RESPONSIBILITY OF THE MENTALLY SUBNORMAL

Perhaps there is no concept which needs a more thorough revision than that of social and legal responsibility. According to the old theory, accepted alike in psychology and in law, human beings could be divided into two absolutely distinct classes, the sane and the insane, the one completely rational and completely responsible, and the other completely irrational and completely irresponsible. It followed, then, that society could protect itself perfectly against any antisocial acts on the part of the first class by attaching to such transgressions penalties sufficient to outweigh the advantages derived therefrom; and it followed just as logically that such penalties were of no avail against the second class.

Unfortunately for the theory, human nature persists in escaping from rigid categories. On the one hand, we find that many of the mentally subnormal are capable of responding rationally, in greater or less degree, to incentives supplied by rewards and punishments; and, on the other, experience shows that normal man at his best is, as some one has put it, a reasoning but not a reasonable animal—still less the ratiocinating machine presupposed by the theory of our penal system. Responsibility is not, as was once supposed, an indivisible unit, but rather a web into which enter strands from many sources.

The idea that an insane man should be subjected to what is ordinarily called punishment seems revolting to many persons. Criminal jurisprudence appears to rely on the maxim that any degree of mental aberration in an individual renders him altogether irresponsible in all his conduct, especially if this be criminal. The theory of partial or attenuated responsibility, though held by some eminent physicians, among whom may be reckoned the late Dr. C. F. Folsom, of Massachusetts, appears to have taken comparatively slight hold on the public or the legal mind. Hence it is not strange that a recent paper by Dr. J. J. Walsh[1] should have been editorially criticized by some newspapers as barbarous in its ideas and in its possible influence on the practice of the criminal courts. If it be recognized, however, that punishment is not based on any other fundamental consideration than the protection of society, it is difficult to see why it should not be inflicted in some cases of insanity. "Insanity" is a term of extremely wide interpretation; and we may rationally assume that it is not in all its degrees equivalent to irresponsibility. Walsh's assertion that punishment would be more deterrent to the partial lunatic than to the normal individual may need considerable qualification. Cases differ widely, and some subjects of morbid impulse, for example, not to speak of subjects of delusion, may be utterly incapable of being deterred by any penalty whatever. It is only a part of the insane who fall correctly into his class of mentally subnormal individuals who really can control their evil impulses if sufficient incentive is given. With a large proportion of them, however, there is some susceptibility to control of this kind, and even in the best-managed asylums, where the word "punishment" is tabooed absolutely, this fact is practically recognized and discipline maintained by classification of the patients and other means. Even epileptic furor is, in some cases at least, capable of control by fear of consequences. Some of the most violent epileptics will be very careful not to attack or to interfere with other patients whose physical strength is greater than their own. Many of the crimes of the insane are committed with a full knowledge that they are protected from the consequences by the theory of their irresponsibility. Nevertheless, society has to be protected from them as from other criminals; Dr. Folsom, in his comments on the case of Jesse Pomeroy, expressed the same idea even more strongly than Dr. Walsh, when he asks whether anything else than death will protect society from such an individual as Pomeroy when the chances of escape from prison are so many.

[1] Bulletin 53, Hygienic Laboratory, U. S. Public Health and Marine-Hospital Service, Washington, D. C., 1909; also Jour. Pharmacol. and Exper. Therap., August, 1909, p. 185.

[1] Walsh, James J.: Insanity, Responsibility and Punishment for Crime, Am. Jour. Med. Sc., August, 1909, cxxxviii, 262.

It is not necessary to go so far as to demand the death penalty in cases of doubtful or attenuated responsibility; but officials who have the pardoning power and judges of courts should be held to a stricter responsibility in such cases than even in ordinary ones. Mental weakness in a criminal is itself a source of danger; what makes him an unfit subject for extreme punishment also renders more perilous the enlargement of his privileges. There are many criminals of whose mental soundness there may be some doubt, but who need, for the security of the public, to be put under more effective restraint than that afforded by any ordinary institution for the insane. Even a so-called criminal asylum may not be sufficiently secure. When such an individual has committed the highest crimes he should be deprived of physical liberty for life. This may be contrary to the present tendency. Many physicians, especially some experts in insanity, will not agree with it, but it is a rational, and, to some of the best alienists, the only possible solution of the problem. The death penalty is not justifiable in cases in which there is any doubt of the responsibility of the individual, but punishment short of that, and, especially, humane and secure confinement for life, seems the proper treatment for those who escape the extreme penalty of the law on the ground of insanity.

THE USE OF MILK AS FOOD

Milk is so important an article, from both the dietetic and the commercial points of view, that the results of an experimental and statistical investigation on the subject made by Mr. R. D. Milner,[1] Assistant in Nutrition Investigations of the United States Department of Agriculture, must prove of great practical interest, even though they convey nothing really new.

In the first place, milk and its derivatives supply about 16 per cent. of the food-value of the average American family diet. Of this amount, approximately one-third is used in the form of milk and cream, the remaining two-thirds being converted into butter and cheese. From economic and climatic considerations especially, the cow is the source of most of the world's supply of milk, although in different places the goat, the buffalo, the llama, the camel, the mare, the sheep and the reindeer also make their contribution to the milk supply.

The composition of milk varies between rather wide limits, although a good unadulterated article should contain about 87 per cent. of water and 13 per cent. of solids; about one-quarter of the solids consists of protein compounds (5 or 6 parts of casein to 1 part of albumin) and one-third of fats. The fat of milk is present in the form of an emulsion, and the creaminess depends on the size and number of the fat-globules. Carbohydrates, of which lactose is the most important, comprise 38 per cent. of the solids; the remaining solids consist of mineral matters, principally phosphates and chlorids (sodium, potassium, calcium).

Milk almost invariably contains bacteria of varied kind and number; some of these cause the souring of milk and the ripening of cream and cheese and are responsible for other changes affecting both the appearance and the flavor. Milk may also be the carrier of pathogenic germs, notably those of typhoid fever, scarlet fever, diphtheria and tuberculosis. In the absence of bacteria, milk would remain sweet indefinitely, and the problem of milk-preservation consists in checking the growth and multiplication of bacteria. These are comparatively inactive at a temperature below 50° F., but they are not destroyed by freezing, which brings about undesirable changes in the milk, while extreme heat kills them and causes other undesirable changes. Pasteurization and sterilization are useful means of controlling the growth of bacteria. As the process of manufacture destroys any bacteria which may be present, condensed milk and milk-powders are practically sterile. The use of chemical agents for the purpose of destroying bacteria in milk is not to be commended. In many large cities standardized and certified milks can be obtained.

The nutritive materials of milk are easily and thoroughly digested by normal, healthy persons, and often even by persons of impaired health. By many observers the protein is believed to be rendered less easy of digestion by boiling. The digestibility of the fat appears to depend inversely on the size of the fat-globules. Mother's milk is best adapted by Nature to the nourishment of infants. It differs from cow's milk mainly in the character of its protein, in the smaller size of its fat-globules and in its greater amount of milk-sugar. Milk contains too much water to be a perfect food for adults; nevertheless, its solids furnish all the necessary ingredients and in good proportions.

---

[1] Farmers' Bulletin No. 363.

Unless the price be exceptionally high, milk is as economical a source of nutrients as other animal foods, but less so than most staple vegetable products. On the other hand, it requires no preparation, is free from waste and is more thoroughly digested than most vegetable foods. As a source of protein, the most expensive of the nutritive ingredients, it is especially economical. Skim-milk, which is the whole milk minus part of its fat, and which costs only half as much as whole milk, furnishes protein at one-quarter the price of beef; and, as fat is usually abundant in the ordinary mixed diet, skim-milk might most advantageously be used in the place of whole milk in dietaries in which cost must be carefully considered. The freer use of skim-milk for cooking purposes is also to be recommended. Foods prepared with either whole milk or skim-milk are by so much the more nutritious than if prepared with water.

Butter and cheese are the most important products of milk. Butter is one of the chief sources of fat in the ordinary diet and furnishes it in a palatable and easily digestible form. Cheese consists of the casein of milk plus more or less of the fat and mineral matters. Its flavor and texture vary with the bacteria and ferments developed in the process of manufacture; the less expensive varieties make one of the cheapest sources of protein. The common and milder varieties are easily and thoroughly assimilated. Other products of milk—junket, whey, buttermilk, clabber and the fermentation-products, such as kefir and kumiss—are all nutritious foods and are often of especial value in the diet of invalids.

BILE SALTS

During the last few years there has been marked interest in the use of bile salts as medicinal agents. In discussing the question of the action and use of the bile salts it should be clearly understood that they are not in any proper sense a new introduction into therapeutics. They are, in fact, merely a different form of a remedy that has had a place in medicine for a long time and which now is official in the United States Pharmacopeia as Ox Gall (Fel Bovis) and Purified Ox Gall (Fel Bovis Purificatum). Bile salts are merely the active constituents of the bile and will find their therapeutic application wherever the bile itself might be used. Since their only advantage over bile lies in the fact that they are free from extraneous matter, the question of purity is of great importance. It is regretable to learn, as the analyses of Long and Johnson[1] clearly show, that some preparations on the market are deficient in this respect. Bile and pure bile salts deserve a more thorough and critical clinical trial than has been accorded them in the past, and their sphere of usefulness needs to be determined more exactly. They are regarded by some as the most powerful stimulant of the secretion of bile which we possess, though it should be noted in this connection that some pharmacologists hold that the increase in bile salts excreted simply represents the amount of bile salts administered and excreted in addition to the normal amount contained in the bile.[2] If this is true the amount of increase in the secretion will depend on the dose and can not be expected to be very great on the doses recommended for some of the preparations. Since these products are being used in large quantities, an investigation, such as that by Long and Johnson, should prove of great value.

THE ITALIAN CONGRESS ON PELLAGRA

In view of the recent recognition, the wide distribution, and the apparently increasing prevalence of pellagra in this country, the work of the fourth Italian congress on pellagra, which has just concluded its sessions at Udine, is of much importance here. G. Sanarelli, president of the congress, professor of hygiene at Bologna, and undersecretary of the Italian department of agriculture, supports Lombroso's theory in regard to the etiology of the disease, and believes that the chief obstacles to the eradication of pellagra in Italy are the ignorance of the peasantry, among whom "polenta," or thick corn-meal mush, is a universally popular dish, the culpable inertia of the large landed proprietors and their agents, and the cheating of the millers, who make a practice of substituting defective maize for good grain brought to their mills to be ground. The Italian government, like the Austrian government,[3] has been making special efforts to stamp out the disease by instruction in regard to diet and prophylaxis as well as by hospital treatment, and now intends to establish a system of supervision for the milling of maize. It is interesting to note that in Italy pellagra is attributed especially to the use of corn grown in situations which do not permit the ear to come to full maturity. A similar suggestion has been made in regard to the disease in this country. McCampbell[4] believes that the increase of pellagra here may be due to the fact that, whereas it was formerly the custom to allow the ear to stand in the field on the stalk until perfectly mature and dry, it has lately become a common practice to cut the corn-stalk, often immature and green, and to pack it in a shock, where conditions favor fermentation and heating. It will be of interest and value to compare the results of the Italian congress with those of the National Conference on Pellagra in this country, which meets in Columbia, S. C., early in November.

Medical Inspection of Schools.—The departments of school hygiene should cooperate with boards of medical inspection in detecting and preventing contagious diseases. The boards of medical inspection become especially active during times of epidemic and contagion, but the departments of school hygiene should never cease their activity while children are growing. Like the parent and the teacher theirs should be a constant care, the value of which is to be measured only by the influences of time and the tests which measure true service.—G. W. A. Luckey, in *Hygiene and Physical Education.*

Medical News

ALABAMA

Colleges Open.—Birmingham Medical College opened for its winter term September 29. The opening address was made by the Rev. J. T. Plunkett, D.D.——The annual session of the Medical Department of the University of Alabama, Mobile, opened September 22. Addresses were delivered by the dean of the faculty, Dr. Rhett Goode, and President J. W. Abercrombie of the University.

Personal.—Dr. Montgomery G. Shipp has been elected health officer of Albertville, Dr. James A. Thomson of Guntersville, and Dr. David A. Morton of Boaz.——The Dallas County Board of Health has chosen Dr. Thomas G. Howard, Selma, county health officer, vice Dr. Barney B. Hogan, removed from the city. Dr. James S. Chisholm was elected secretary of the board.——The governor has remitted the fine of $10 against Drs. Joseph N. Guy, Lapine, and W. H. Mitchener, for failure to transmit vital statistics as required by the new state medical regulations.

COLORADO

Personal.—Dr. Benjamin F. Griffith, Leadville, has been elected grand physician of the Women of Woodcraft.——Dr. Thomas A. McIntyre, Cripple Creek, is reported to be seriously ill with septicemia.

Hospitals Acquire Property.—The State Land Board has given 310 acres of farm land in Jefferson county to the state as a site for the State Home and Training School for Feeble-Minded Children, the bill establishing which was passed by the last legislature.——The Children's Hospital Association, Denver, has bought the property at Twenty-second and Downing avenues, formerly occupied as the Woman's Hospital. The building has a capacity of 25 beds and will be ready for use November 1.

State Society Meeting.—At the annual meeting of the Colorado State Medical Society in Estes Park, September 14-16, the following officers were elected: President, Dr. Leonard Freeman, Denver; vice-presidents, Drs. John R. Espey, Trinidad, Allan J. McDonald, Leadville, Ella Avery Mead, Greeley, and Samuel C. Halley, Fort Collins; councilors, Drs. Edmund J. A. Rogers, Denver, and George H. Cattermole, Boulder; delegate to the American Medical Association, Dr. Hubert Work, Pueblo; alternate, Dr. Alexander C. Magruder, Colorado Springs, and member of publication committee, Dr. Henry W. Hoagland, Colorado Springs. Colorado Springs was selected as place of meeting for 1910. A resolution was adopted setting forth the faithful and conscientious labor of the editor of *Colorado Medicine*, Dr. George A. Moleen, Denver, and extending the thanks of the society to him. Dr. Melville Black, Denver, presented a resolution, which was carried, urging a careful inquiry into the advisability and feasibility of the establishment of a sanatorium and home to be maintained by the American Medical Association for the care of its members.

DELAWARE

Sanatorium Dedicated.—Beth Israel House, the gift of the Jews of Wilmington to the Delaware Antituberculosis Society, was dedicated October 10, at Hope Farm.——At the same time the Baron De Hirsch shack, the gift of Nathan Garsky to the society, was dedicated. Previous to the ceremony, members of the Delaware Red Cross, the Antituberculosis Society, and the legislature were entertained at a banquet, at which the governor and other prominent personages made addresses.

Officers Elected.—At the one hundred and twenty-first annual meeting of the Medical Society of the State of Delaware, held in Dover, October 12, the following officers were elected: President, Dr. Presley S. Downs, Dover; vice-presidents, Drs. L. Heisler Ball, Marshallton, and Joseph M. Martin, Lewes; secretary, Dr. George W. K. Forrest, Wilmington; treasurer, Dr. Samuel C. Rumford, Wilmington; delegate to American Medical Association, Dr. James H. Wilson, Dover; and delegate to National Council on Medical Education, Dr. Henry W. Briggs Wilmington.

ILLINOIS

Hospital Opening.—A reception was given, October 4, by the Physicians' Club of Canton to the Graham sisters, who donated Graham Hospital to Canton, and the public reception and opening of the hospital was held on the following day.

Personal.—Dr. Benjamin J. Nauman, Peru, George W. Boot, Evanston, and William B. Peck, Freeport, have returned from Europe.——Dr. Sidney G. Pratt, Buda, who recently underwent operation in St. Francis Hospital, Kewanee, is reported to be convalescent.

Norbury Given Loving Cup.—At a meeting of the Jacksonville Medical Club, October 2, Dr. Frank Parsons Norbury, recently appointed superintendent of the Kankakee State Hospital, was presented with a handsome loving cup by the club. The speech of presentation was made by Dr. Albyn L. Adams.

Pellagra Commission Named.—The governor has appointed the following committee to investigate pellagra: Drs. Frank Billings, George W. Webster, Howard T. Ricketts, and Oliver S. Ormsby, Chicago; Dr. James L. Greene, Springfield; Dr. H. Douglas Singer, Kankakee; Drs. Harris S. Grindley and Ward J. McNeil, Urbana.

Pellagra Conference.—The following will constitute the committee from Illinois, delegated to attend the Conference on Pellagra, to be held at the State Hospital for the Insane, Columbia, S. C., November 3 and 4: Dr. James A. Egan, Springfield, secretary of the Illinois State Board of Health, chairman; Drs. George W. Webster, Frank Billings, and Walter H. Buhlig, Chicago; Dr. John T. McAnally, Carbondale; Dr. H. Douglas Singer, Hospital, and Dr. George A. Zeller, South Bartonville.

Court Verdicts.—Sarah E. Wood, Rock Island, charged, on complaint of the State Board of Health, with practicing medicine without a license and selling drugs and ointments, is said to have been found guilty, October 6, and fined $100 and costs. An appeal was taken.——In the case of Mrs. Carrie A. Smith, Bloomington, against Dr. Ernest B. Mammen, in which negligence in a surgical operation was alleged, the jury is said to have found for the plaintiff, October 9, and assessed damages at $2,400.

Tuberculosis Exhibit.—The State Board of Health made a striking exhibit of the prevalence of tuberculosis and the method of its prevention at the state fair. A striking part of the exhibit was a clock placarded, "Every time this clock strikes some one in Illinois dies of consumption, one every hour, 24 every day, 750 every month, and 9,000 every year." A large chart was exhibited showing the proportion of deaths from pulmonary tuberculosis in the state during stated age-periods for the year 1908. Another noteworthy illustration was a map showing twenty states, in every one of which the legislature has made adequate appropriation for a state sanatorium for tuberculosis, but in which Illinois does not appear. Many warning notices were displayed condemning the habit of spitting. This is the first time the Illinois State Board of Health has prepared such an exhibit for the state fair, and the board cannot be too highly commended for the time and care taken to bring these important truths before the people of the state.

Chicago

Plans to Eliminate Diploma Mills.—The Civic Federation announces its intention of actively undertaking a campaign against illegal medical schools and "diploma mills."

Civil Service Examination.—The County Civil Service Commission announces an examination October 28, to fill the position of chief of the medical staff at the Cook County Institutions, Dunning.

Personal.—Dr. Walter W. Hamburger, Dr. and Mrs. Cassius C. Rogers, and Dr. Henry Gradle have returned from Europe. ——Dr. Otto L. Schmidt has been appointed by the governor a trustee of the Illinois State Historical Library.——Dr. and Mrs. Irvin S. Koll and Dr. Strother J. Beeson have sailed for Europe.——Dr. Frederick O. Tonney has been appointed superintendent of the municipal laboratory, vice Dr. Joseph F. Biehn.

New Hospitals.—More than two hundred patients at the Dunning Tuberculosis Hospital will be removed to the new hospital on the grounds of the County Hospital this month. The hospital has recently been completed at a cost of $150,000, and it is proposed to remove there all the far advanced patients, retaining the more hopeful cases in the institution at Dunning.——Ground was broken, October 10, for the new addition to the Norwegian Lutheran Deaconess' Home and Hospital, which is to cost $75,000, and which is expected to be completed next spring.

Bequests.—Public charities are benefited $382,500 by the will of the late Mrs. Nelson Morris. Of this, $300,000 is left for the founding or endowment of a convalescent hospital or home for children. This bequest is made to any hospital or corporation in Chicago, but preferably to Michael Reese Hospital. The Chicago Home for Incurables receives $5,000; the [illegible] berculosis Sanatorium $5,000; the Chicago [illegible] and Dispensary, $2,500; the Children's [illegible], $5,000, and Michael Reese Hospital

$10,000.——A check for $1,000 has been presented to the German Hospital, Chicago, by Herman Paepcke, in memory of his wife, who died recently.

INDIANA

Personal.—Hope Hospital, Fort Wayne, has secured Dr. Henry Woodring, Altoona, Pa., as house physician.——Dr. Robert M. Campbell, West Point, has succeeded Dr. William S. Campbell, Lafayette, as secretary of the Tippecanoe County Board of Health.

New Health Rules.—The new "Book of Instructions to Health Authorities," issued by the State Board of Health, contains all the laws relating to public health, and is to be furnished to each county health officer, county judge, county auditor, and prosecuting attorney.

License for Medicine Venders.—The Jeffersonville city council, on October 4, passed an ordinance fixing a license fee of $50 for itinerant venders of medicine on the streets, with penalty for each violation of the ordinance, of a fine of not less than $50 or more than $200.

KANSAS

Must Make Reports.—Sedgwick county is to be the seat of war on physicians who do not obey the state health laws as regards the reporting of births, deaths and contagious diseases. The State Board of Health has instructed Dr. Walton I. Mitchell, Wichita, county health officer, to institute proceedings against physicians who fail to obey the law.

Enjoins Registration Board.—Dr. Charles A. Ruggles, Stafford, has brought suit against the Kansas State Board of Medical Registration and Examination to enjoin it from trying him October 14. He alleges that the board issued him a certificate in 1901, and that he has been practicing ever since in Stafford. A temporary restraining order has been granted.

Freak and Quack Doctors.—In order to protect the people of the state against freak and quack doctors, so-called "magnetic healers," etc., the secretary of the State Board of Medical Registration and Examination has secured an official opinion from the attorney-general, which authorizes the board to inaugurate a campaign against fraudulent practitioners in the state. The opinion of the attorney-general is that so-called "magnetic healers" and practitioners of similar systems are barred by the new law, and that an individual comes within the provision of the statute who treats or attempts to treat the sick or those afflicted with bodily or mental infirmities. The board desires all reputable physicians to report any violation in their locality, and promises that arrests will follow promptly. Dr. Henry A. Dykes, Lebanon, is president of the board, and Dr. Frank P. Hatfield, Olathe, secretary.

MARYLAND

State Hospital Inspected.—The State Lunacy Commission and Board of Managers of the Maryland Hospital for Insane, Catonsville, held a joint meeting, October 15, and inspected the institution. The board has acquired possession of a farm of forty-five acres.

Baltimore

Manufacturing Pharmacist Dies.—Mr. Alpheus P. Sharp, founder of the drug firm of Sharp & Dohme, who retired from business a number of years ago, died at his home in Baltimore, October 10, aged 86.

To Examine North Pole Data.—Dr. Ira Remsen, president of the National Academy of Science, has been formally requested by the National Geographical Society to appoint a commission to examine into and report on the data of Commander Robert A. Peary and Dr. Frederick A. Cook, regarding their claims to the discovery of the North Pole.

Personal.—Dr. Nathaniel G. Keirle, superintendent of the Pasteur Institute of the College of Physicians and Surgeons, was given an anniversary dinner, October 11, in celebration of his seventy-sixth birthday, and was presented a volume containing his collected writings on rabies.——Dr. George B. Reynolds is ill at Johns Hopkins Hospital with nervous breakdown.

MASSACHUSETTS

Hospital Opened.—The new Rufus S. Frost Hospital, Chelsea, was opened for inspection October 11. The building is of brick and concrete, 160 by 67 feet, and three stories in height, and has accommodation for 70 patients. Dr. E. Frank Guild is chief of the medical staff of the institution.

Good Health Exhibition.—An exhibition illustrative of the means and methods of the preservation of good health was held in the City Hall, October 13-20, inclusive, under the auspices of the Lawrence Antituberculosis League. The exhibition was held throughout the day, and lectures were given each evening and Sunday afternoon, on the fundamental facts regarding tuberculosis and public health.

Personal.—Dr. Edward H. Bushnell, Quincy, sustained a serious electric shock and burns of the left hand while attempting to turn off the electric light while using the telephone at his home.——Dr. Charles G. Carleton has been reelected president, and Dr. Frank B. Flanders, secretary of the medical staff of the Lawrence General Hospital.——Dr. Earnest D. Pillsbury, West Somerville, sustained painful bruises when a wooden electric light pole fell on his automobile recently.——Dr. Edwin Katzenellenbogen has been appointed lecturer in abnormal psychology in Harvard University.

Few Accept Rebates on Prescriptions.—The committee on rebates on prescriptions, appointed by the Essex North District Medical Society, reported at the meeting, October 13, to the effect that the committee had obtained unquestionable evidence that members of the society and probably other physicians, have been approached to accept rebates on prescriptions and to become interested in the sale of proprietary remedies, but that for the most part these affronts have been treated as they deserve. Any physician who is in doubt as to the proper course to pursue, the committee advises to consult Chapter II, Section 8 of the Principles of Medical Ethics of the American Medical Association and paragraph 7 of the Code of Ethics of the Massachusetts Medical Society.

MICHIGAN

Society Meeting.—At the annual meeting of Ottawa County Medical Society, held in Holland, the following officers were elected: President, Dr. Thomas G. Huizinga, Zealand; vice-presidents, Drs. Daniel G. Cook, Holland, and Julius F. Peppler, Byron Center, and secretary-treasurer, Dr. George H. Thomas, Holland.

Health Campaign in Escanaba.—Dr. Oscar C. Breitenbach has been appointed city chemist of Escanaba. Dr. Breitenbach has been active in the fight against typhoid fever in Escanaba, and has had the earnest cooperation of the Business Men's Association, the mayor and city council. A six million gallon mechanical filter will soon go into commission, and an ordinance providing for the tuberculin test of milk and general milk inspection is now being drafted.

Personal.—Dr. Myron A. Patterson, city physician of Albion, is reported to be ill with typhoid fever in Hurley Hospital, Flint.——Dr. F. J. Bierkamp, Wyandotte, has been appointed pathologist at Youngstown (Ohio) Hospital.——Dr. William DeLano, health officer of Grand Rapids, has relinquished the management of the tuberculosis sanatorium on account of ill health.——Dr. Orley M. Vaughan, Covert, has been unanimously re-elected, for the fifth term, president of the Board of Superintendents of the Poor of Van Buren county.

Adds to List of Communicable Diseases.—At the quarterly meeting of the State Board of Health, held in Lansing October 8, the following diseases were declared to be dangerous communicable diseases: Pneumonia, tuberculosis, typhoid fever, meningitis, diphtheria, whooping cough, scarlet fever, measles, and smallpox. The board also ruled that tetanus, rabies, erysipelas, leprosy and cancer should be reported for statistical purposes. It was decided that no person with open tuberculosis should be employed as a teacher in the public schools of the state, and a resolution was adopted instructing the secretary to prepare and issue notices to common carriers and schools forbidding the use of the common drinking cup.

NEBRASKA

Personal.—Dr. W. H. Wilson, Omaha, has been reappointed State Health Inspector.——The Pathological Club of the University of Nebraska gave a dinner at Lincoln Hotel, September 14, in honor of Dr. Henry B. Ward, formerly dean of the medical college of the university, and elected him an honorary member of the society, the first so to be honored.——Dr. Robert H. Walcott has been appointed acting dean of the college of medicine.

Quarantine Against Meningitis.—The State Board of Health has adopted a resolution setting forth that cerebrospinal meningitis, poliomyelitis, or spotted fever, which is epidemic in certain parts of the state, is recognized by the board as a contagious disease, and is subject to the quarantine laws of the state. Local authorities are ordered to quarantine those who have been exposed, for a period of ten days, the usual period of incubation, and those infected with the disease for a period of not less than twenty-one days.

Society Meeting.—At the semi-annual meeting of Knox County Medical Society, held in Bloomfield, Dr. Czar C. Johnson, Creighton, was appointed secretary pro tem. The question of a uniform schedule of fees was discussed and a committee of three was appointed to formulate such a schedule, to be signed by all members of the society, Drs. Roy Crook, Winnetoon, James R. Kaylor, Bloomfield, and William H. Britt, Creighton, were appointed as this committee. The next meeting of the society will be held in April, 1910, at Creighton.

Southeastern Physicians Organize.—A meeting of physicians, representing southeastern Nebraska, was held at Tecumseh, October 6, at which the southeastern Nebraska Medical Society was organized, with Dr. Earl B. Brooks, Pawnee City, president, and Dr. Albert P. Fitzsimmons, Tecumseh, secretary. The district of the society includes Gage, Pawnee, Johnson, Richardson and Nemaha counties.

NEVADA

State Society Meeting.—The sixth annual meeting of the Nevada State Medical Association was held in Goldfield, October 5-7. The following officers were elected: President, Dr. George McKenzie, Reno; vice-presidents, Drs. Francis M. Nesmith, Goldfield, and William H. Hood, Reno; and secretary-treasurer, Dr. Sidney K. Morrison, Reno. The next meeting will be held at Lake Tahoe.

NEW JERSEY

Must Register Births.—Under the new state law on vital statistics, which went into effect October 1, physicians and midwives are required to file certificates of birth with the city clerk within five days, under a penalty of $50 for each violation. Under the new law, the city receives twenty cents for every birth or death reported.

Elections.—At the meeting for organization of the Woodbury Society for the Prevention and Relief of Tuberculosis, the following officers were elected: President, William T. Cooper; vice-presidents, Mrs. Elizabeth Cooper, Miss Elizabeth Matlack, and Mrs. Charles Eastlack; secretary, Howard S. Davis; treasurer, Dr. Thomas E. Parker, and solicitor, A. L. Rogers. ——At the annual meeting of the Practitioners' Society of East Monmouth, October 8, Dr. William B. Warner, Red Bank, was elected president; Dr. Reginald S. Bennett, Asbury Park, vice-president; Dr. Harry E. Shaw, Long Branch, secretary, and Dr. William K. Campbell, Long Branch, treasurer.

Fewer Deaths in September.—During the month ended September 15, 3,153 deaths were reported, a decrease of 102 from August, and of 311 as compared with September, 1908. The decrease in mortality is in a great measure believed to be due to the efficient work of local health authorities. Chief among death causes for the month were infantile diarrhea, 553; diseases of the nervous system, 343; diseases of the circulatory system, 317; tuberculosis, 302; diseases of the digestive system, 257; nephritis, 204; cancer, 119; diseases of the respiratory system, 115; pneumonia, 93; whooping cough, 33; suicide, 32; diphtheria, 31; typhoid fever, 23; cerebrospinal meningitis, 18; scarlet fever, 11; measles, 7, and malarial fever, 6.

NEW YORK

Hospitals Consolidate.—Action has been taken consolidating the New York Infant Asylum and the Nursery and Child's Hospital, both of New York City. The institutions have combined assets of $1,000,000.

New Superintendent.—Dr. William T. Shanahan, Sonyea, who for nearly nine years has been a member of the medical staff of the Craig Colony for Epileptics, has been appointed medical superintendent of that institution.

A Million for Charity.—A New York philanthropist, whose name is withheld, has written, through his attorney, asking Dr. Robert W. Hill, secretary of the State Board of Charities, for advice as to the best way to distribute one million dollars for charity in this state or in New Jersey.

Medical College Opens.—The formal opening exercises of the College of Medicine of Syracuse University were held October 6. Dean Smalley, of the university, delivered the opening address on "The Value of a Liberal Education," and Dr. John L. Heffron, dean of the Medical College, spoke on the development of medical science in the last fifty years.

New York City

Ambulances in Collision.—Three ambulances belonging to the J. Hood Wright Hospital were damaged in collisions on three consecutive nights. In two of these accidents the ambulance surgeons and drivers were severely cut and bruised.

Open-Air School Rooms Wanted.—The Department of Education, in addition to the sum of $3,400 asked for the instruction of tuberculous children, has asked for $6,500 to build and equip open-air school rooms for anemic children.

A More Vigorous Antituberculosis Fight.—The representatives of seventy-five civic and charitable institutions met at the Colony Club to discuss the 1910 city budget. Lawrence Veiller stated that the death rate from tuberculosis had not decreased in this city since 1902 and that it would be greater this year than for several years past. The Board of Health has on its register 48,000 cases of tuberculosis; 28,000 of these are not receiving any medical attendance and 20,000 patients have been lost sight of during the last two or three years; their fate is unknown. The Board of Health is doing its best with limited funds but needs $250,000 at once. With this fund it will be possible to provide only one visit a month by a physician and a nurse to each patient. For the sanitarium at Otisville, Riverside Hospital and Bellevue and the Allied Hospitals more money is needed, hence a resolution was offered urging the Board of Estimate and Apportionment to grant an increase of $487,250 for the campaign against tuberculosis, $362,169 for municipal charities and hospitals and $6,800 for Bellevue and the Allied Hospitals.

PENNSYLVANIA

Auto Ambulance.—An automobile ambulance has been purchased by the city of Harrisburg. The ambulance will accommodate four patients in addition to the necessary attendants.

New Hospital Opened.—The new hospital, recently erected in Nanticoke, at a cost of $30,000, was formally opened October 12. The dedicatory address was delivered by Lieutenant-governor Murphy.

District Society Meeting.—At the annual meeting of the Fourth Censorial District Medical Society, held in Harrisburg, September 16, Dr. George W. Berntheizel, Columbia, was elected president, and Dr. Chester F. Markel, Columbia, secretary.

Physicians Arrested.—Sixty physicians of Schuylkill county were placed under arrest October 2 by Dr. R. J. Brauner, state inspector of health, charged with violation of the act of 1905, which requires that births of all children be reported within ten days.

New School Building.—It is announced that plans for the new building of the Medical Department of the University of Pittsburg will be completed and construction will be started this month. The new building will be located at the extreme west end of the grounds of the university and almost at the highest point.

Vaccination Upheld.—In an opinion handed down in Common Pleas Court, by Judge J. J. Miller, of Pittsburg, the right of the authorities of the State Department of Health, through Dr. Samuel S. G. Dixon, Commissioner of Health, and his advisory board, to regulate vaccination in the public schools of this state, is upheld.

Tuberculosis.—More than $20,000 was collected in Reading, September 20, by Berks County Tuberculosis Aid Society. ——The new buildings of the Jewish Consumptive Sanatorium Association at Eagleville were dedicated October 10. A fund of $6,500 toward the maintenance of the institution was pledged at the dedication exercises.

Tuberculosis Pavilion.—Through the generosity of Hon. James R. and Mrs. Macfarlane, a fresh-air pavilion for tuberculous patients is to be added to the Pittsburg Hospital for Children, in memory of a child of the donors, who died several years ago. The pavilion is of the one-story bungalow type, and will cost, when completed, about $3,000.

Personal.—Dr. William S. O. Sherman, Pittsburg, has been appointed chief of the surgical staff of the Carnegie Steel Company.——Dr. John F. McGrath, medical examiner for the bureaus of police and fire, Pittsburg, has resigned.——Dr. James E. Silliman, Erie, was operated on recently at Jefferson Hospital, Philadelphia, for ventral hernia.

Acquitted.—Dr. Condy C. Gallagher, Coaldale, charged with the illegal practice of medicine, was acquitted.——In the case of Drs. John C. Weidman and Anthony I. Hoon, Mercer, charged with sending anonymous communications through the mails, libeling Lyle W. Orr, the jury decided in favor of the defendants, the prosecutor to pay the costs.

Dr. Weeks Vindicated.—At a meeting of the Board of Trustees of the Eastern Pennsylvania Institution for Feeble-minded and Epileptics, Spring City, October 13, Dr. Henry M. Weeks, the superintendent, was vindicated of the charges of mismanagement made against him. The full board, after going over the evidence, declared the charges untrue and furthermore declared their confidence in the superintendent.

First-Aid Contests.—First-aid teams of six coal companies competed at Wilkes-Barre, October 2, for the prizes offered by the American National Red Cross. The judges of the contests were Major Charles Lynch, Major Charles R. Reynolds and Captain Howard B. Bailey, Medical Corps. U. S. Army. The first prize was won by the Pennsylvania team, the second by the Hillside team, and the third by the Susquehanna team.

Physicians Honored.—At the annual meeting of the Erie County Medical Society, held in Girard, September 21, the birthday of Dr. Orlando Logan, the oldest physician in the organization, was celebrated. In token of the esteem in which he is held, he was presented with a cane, Dr. E. H. Strickland making the presentation address.——At a reception given by the State Board of Medical Inspectors at the home of Dr. Samuel G. Dixon, State Commissioner of Health, Bryn Mawr, a silver loving-cup was presented to Dr. Dixon, Dr. Edgar M. Green making the presentation speech.

Public Health Education.—The meeting of the Pennsylvania Branch of the Public Health Education Committee of the American Medical Association was held in Philadelphia September 28, at the time of the meeting of the State Medical Society, Dr. Elizabeth Leiper Martin, Pittsburg, state secretary for Pennsylvania, presiding. Dr. Rosalie Slaughter Morton, New York City, chairman of the National Committee, described the origin and aims of the committee, which was formed at the request of the House of Delegates of the American Medical Association for the purpose of educating the public, through various women's organizations, in the prevention of disease. Plans for work in Philadelphia and all over the state were outlined by Drs. Francis C. Van Gasken, Philadelphia, and Dr. Martin. The unanimous spirit of enthusiasm was most gratifying and it was felt by those present that great good might result from this movement of women members of the American Medical Association. The House of Delegates of the State Society passed a resolution endorsing the work of the committee, and authorizing a public health and education committee in every county in the state.

Philadelphia

Officers Elected.—At a meeting of the Pathological Society, October 15, the following officers were elected: President, Dr. David Riesman; vice-presidents, Drs. Aloysius O. J. Kelly, Alleen J. Smith, David L. Edsall and Joseph Sailer; secretary, Dr. Edward H. Goodman; treasurer, Dr. Courtland Y. White; recorder, Dr. Frederick H. Klaer, and curator, Dr. Howard T. Karsner.

Personal.—Dr. Harry Lowenburg has been elected pediatrist of the Northwestern General Hospital.——Drs. Benjamin L. Gordon and John H. Musser have returned from Europe.——Dr. Gerald D. O'Farrell was thrown from a carriage in a runaway October 4, fracturing his clavicle and sustaining scalp wounds and contusions.——B. Byron Dawson, the newly appointed executive secretary of the Pennsylvania Society for the Prevention of Tuberculosis, has assumed his duties.

College of Physicians to Open.—The new building of the Philadelphia College of Physicians on Twenty-sixth and Ludlow streets will be formally opened November 10. The building will be handed over to the college by Dr. William J. Taylor, secretary of the building committee, and will be accepted by the president, Dr. George E. De Schweinitz. The dedicatory address is to be delivered by Dr. James Tyson, president of the college, and addresses will be delivered by Drs. Robert Fletcher, Washington; John S. Billings, New York City; William Sydney Thayer, Baltimore; Charles L. Dana, New York City, and Reginald H. Fitz, Boston. At the evening session an address will be made by Dr. S. Weir Mitchell, after which a reception will be held.

Tuberculosis Exhibit at Normal School.—The educational exhibit of the Pennsylvania Society for the Prevention of Tuberculosis was opened in the Girls' Normal School, October 18. The principal of the school presided, and addresses were made by Dr. Martin Brumbaugh, director of public schools; Dr. Joseph Neff, director of the Department of Health and Charities, and Dr. Charles Hatfield, president of the Pennsylvania Society for the Prevention of Tuberculosis. The exhibit was open daily from 2 until 3:30 p. m. and was closed October 22. Demonstrations were given each day and the exhibit was composed of material displayed at the exposition held in this city last spring. From the normal school the exhibit will be placed on view at the various public schools throughout the city.

New Milk Rules in Effect.—Rules and regulations for the sale of milk recently adopted by the Board of Health were made effective October 15. One of the rules, in conformity to an act of legislature, provides that every milk dealer and storekeeper who sells milk must be provided with a special license, the cost of which will be $5 per year. This license must be displayed in the dealer's principal place of business and duplicates must be placed in all delivery wagons, and all wagons must be numbered for identification purposes. Selling without license will be punishable by a fine of $50 or imprisonment of not more than one hundred days. License will be revoked for violation of rules, regulations and requirements of the board. Dealers, thus deprived, have the right to appeal within five days to the courts.

WEST VIRGINIA

Personal.—Dr. D. B. Bushong, Summit Point, has been appointed medical examiner of the Baltimore and Ohio Railroad Company Relief Association at Cumberland, Md.——Dr. James L. Massey, Parkersburg, is said to have been fined $50 and sentenced to imprisonment for three months in jail for contempt of court August 31. He is alleged to have failed to pay alimony and to have threatened the life of the judge.

Elections.—At the forty-second annual meeting of the West Virginia State Medical Association, held in Elkins, October 6-8, the following officers were elected: President, Dr. Thomas W. Moore, Huntington; vice-presidents, Drs. Claude L. Holland, Fairmont; James McClung, Richwood, and A. L. Grubb, Berkeley Springs; secretary, Dr. Arthur P. Butt, Davis; treasurer, Dr. Hugh G. Nicholson, Charleston; councilors—first district, Dr. George H. Benton, Chester; second district, Dr. John C. Irons, Elkins; third district, Dr. J. G. Wheeler, Hanford; fourth district, Drs. Lonzo O. Rose, Parkersburg, and Alva S. Grimm, St. Marys; and fifth district, Dr. Joseph E. Rader, Huntington; and delegates to the American Medical Association, Drs. Albert S. Bosworth, Elkins, and Charles A. Wingerter, Wheeling.——The Ohio County Medical Society, at its annual meeting in Wheeling, elected the following officers: President, Dr. John J. Osborne; vice-president, Dr. William S. Fulton; secretary, Dr. Randolph J. Hersey; treasurer, Dr. Reed McC. Baird; and councilors, Drs. Samuel L. Jepson, Charles A. Wingerter and Robert M. McMillen, all of Wheeling.——At the annual meeting of the Barbour-Randolph-Tucker County Medical Society, held at David, Dr. Lurty N. Harris, Mill Creek, was elected president; Drs. Arthur P. Butt, first vice-president, Davis, and E. Mendel Hamilton, Belington, vice-presidents; Dr. T. Jud McBee, Elkins, secretary-treasurer; Dr. John W. Bosworth, Philippi, censor, and Dr. George C. Rodgers, Elkins, delegate to the state medical association.

GENERAL NEWS AND COMMENT

Italian Physician in America.—Prof. Dr. Nicolo De Dominicis, of the University of Naples, is making a second visit to this country and is being entertained in Boston, New York and other cities.

Navy Medical School Opens.—The Naval Medical School opened for its annual session, October 4. The faculty includes Medical Director John C. Boyd, president of the school; surgeons Charles F. Stokes, Frank L. Pleadwell, Eugene J. Grow, and Charles St. J. Butler; passed assistant surgeons. Owen J. Mink and Francis M. Shook, and Lieutenant Commander Downs L. Wilson, retired, instructor in hospital corps drills and signaling.

Bilibid Prison.—In the report of the Bilibid Prison, Manila, for the fiscal year 1909, it stated that the prevailing diseases among the prisoners were helminthiasis, malaria, morphinism. bronchitis, tuberculosis, dyspepsia and dysentery in the order *named.* The deaths during the year amounted to 129, of which 93 were due to tuberculosis, and of these 82 were from pulmonary tuberculosis, while the other deaths from all causes were only 36.

Monument to Dr. Turner.—The American Society for the Study of Inebriety and Narcotics has erected a monument to the memory of Dr. J. Edward Turner, the founder and builder of the first inebriate asylum in the world, at Binghamton, New York. The dedicatory services will be held October 27, at Wilton, Conn. A historic address will be delivered by Dr. H. O. Marcy, of Boston; the dedicatory address by Dr. L. D. Mason, of Brooklyn, and the memorial oration by Dr. T. D. Crothers, of Hartford, Conn. This monument is a tribute to the memory of Dr. Turner from the various inebriate asylums, homes and sanatoriums of the country.

Wants Pay for Correcting an Error.—A well-known pharmaceutical house, which makes vaccine virus as one of its products, prepared and propagated a large amount of virus that the Public Health and Marine-Hospital Service declared contaminated. This was made while the firm was operating under the federal license which is required of all manufacturers of such products. On ascertaining the facts the government suspended this license until the firm had withdrawn all of the contaminated virus from the market. By order of the Public Health and Marine-Hospital Service the product was condemned and ordered destroyed. The company then withdrew the condemned product from the market and destroyed it; the value of the amount destroyed being stated as over $14,000. The firm in question then presented a bill to the government for the amount of the virus destroyed! The bill was not allowed.

The English Sparrow as a Disseminator of Disease.—A correspondent of *Bird Lore*, the organ of the Audubon societies of the United States, includes, among other evil results of the introduction of the English sparrow to this country, its agency in the propagation of disease. She says: "To the dog and cat is often charged the spreading of the infectious germs of swine and poultry diseases. While these animals have one chance to be such carriers, the English sparrow is probably guilty a hundred times in his rôle of gleaner in the hog-pen and poultry yard." The English sparrow has been called "the feathered rat," and it well deserves the name. Its danger to human kind is not altogether negligible, for it is a ubiquitous little creature, and, while it does not enter our habitations directly, it has ample opportunities to communicate any disease germs of which it may be the bearer to our domestic animals and household pets. The germ-carrying capacity of the English sparrow and its relation to public health and disease might make a profitable subject for investigation and study.

Railway Surgeons Meet.—At the annual meeting of the Association of Surgeons of the Southern Railway Company, held in Lexington, October 11, the following officers were elected: Dr. James P. Salb, Jasper, Ind., president; Drs. R. Craig Falconer, Lexington, Ky., and James H. Lacy, Albion, Ill., vice-presidents; Dr. Frederick R. Gobbel, English, Ind., secretary-treasurer, and Drs. Martin F. Coomes, Louisville, Ky., Julien W. Scott, Venice, Ill., and Frederick R. Gobbel, English, Ind., executive committee.——The chief medical examiners of the relief departments of the Pennsylvania Lines, Chicago, Burlington and Quincy, Philadelphia and Reading, Atlantic Coast Lines, Western Maryland, and the Baltimore and Ohio systems met in the offices of the Baltimore and Ohio Railroad, Baltimore, October 9, and organized, to better facilitate the interchange of experience, and in a general way promote the work of the medical and surgical corps under their direction.

Death Causes.—The preliminary report of the Census Commission relative to the second decennial revision of the Classification of Causes of Death, made by the International Commission in Paris, together with a revised list of titles, will be found in Census Bulletin No. 104, soon to be published, and copies will be sent to all the registration officials of the United States and to the members of the American Statistical Association. A new manual of classification will be prepared for the use of registration officers of the United States as soon as detailed results of the revision are available, and an effort will be made to bring the revised classification to the attention of every physician and local registrar in the country, as an aid to the proper reporting of causes of death. Dr. Wilbur states that the United States starts at the beginning of a new census decade with revised classification of causes of death, in which American registration officials and American physicians have had their say; a revised standard certificate of death, which will be adopted by the American Public Health Association, in Richmond, this month, and put into effect Jan. 1, 1910; and with new rules and instructions recently formulated by the Directors of the Census, and promulgated to all reporting officers for the purpose of obtaining more complete and correct transcripts of the deaths now registered.

FOREIGN

Death of Lombroso.—Cesare Lombroso, the noted alienist and criminologist, died at Turin, Italy, October 18, of heart disease, aged 73.

Fourth Latin-American Medical Congress.—The *Brazil Medico* gives the details of this successful gathering of medical men from all the Latin-American countries, held at Rio de Janeiro in August. Dr. A. Sodré, editor-in-chief of our esteemed exchange, was president of the congress, which attracted 1,500 members, and at which over 100 papers were presented. There was an exhibition in connection with the congress, but the most interesting exhibit was the city of Rio itself, which has eradicated yellow fever mainly by the initiative and efforts of Oswaldo Cruz, at the head of the board of health. The congress adopted a resolution congratulating him on this, "the most brilliant sanitary triumph of the contemporaneous epoch."

LONDON LETTER

London, Oct. 9, 1909.

The Education of the Medical Student

The unceasing progress of medical science necessitates constant changes in the education of the medical student and a constant increase in his curriculum. The problem how to teach him all that he should learn becomes more and more difficult. Some years ago it was found necessary to increase the course of study from four to five years, but so difficult is it found that the average time now spent before a qualification is obtained is nearly seven years; only 13.8 per cent. of the students obtain a qualification in the minimum period of five years, 35.9 per cent. take six years, while the remaining 51 per cent. consume seven years or more in getting their medical education. The General Medical Council (the body appointed by government to control medical education and to exercise disciplinary powers over the profession) has had the question under consideration whether it would be expedient to again lengthen the course, either by extending it to six years or by setting back the preliminary subjects of chemistry, physics and biology to a period anterior to the commencement of the medical curriculum proper. A committee appointed by the council to investigate the subject has reported that the length of time now occupied in obtaining a qualification renders further extension of the course undesirable. It does not consider the second alternative feasible at present, partly because the secondary schools of the country, from which the medical students come, are not adequately equipped in sufficient numbers for the purposes of instruction, and partly because it is as much as the medical students now can do to pass the present entrance examination at a reasonable age. The average age of the students is 18½ years. Another important subject discussed was whether the fifth year should be confined to clinical study. When the fifth year was added to the curriculum the object was that it should be devoted entirely to this study, but it often happens that other subjects which the student has not succeeded in completing, are also studied in this year. The committee recommends that no fixed rule be made on the point, and hopes that by better distribution of the work in the earlier years the object intended may be achieved.

London Medical Schools

The opening of the London medical schools this session has been characterized by unusual activity, and the result of recent developments are apparent. Many have enlarged their premises and improved their equipment. The younger schools of the provinces have for some time shown themselves serious competitors, for they are equipped in the most modern fashion and most of them have the advantage of being attached to a university, while the majority of the London medical schools are not. Moreover, the London schools are to a large extent without public endowment, which is a common feature of provincial schools. The advantage of London is the size of its hospitals, which furnish a wealth of clinical material seldom approached in the provincial schools. It is now recognized, however, that much reliance must not be placed on this, and that it is necessary that medical schools be equipped in the most modern manner. Another new feature in the London schools and hospitals is the increasing provision for postgraduate teaching. Twenty years ago no provision whatever existed; now several hospitals are devoted entirely to it, and many others are making or have made arrangements for it. A great disadvantage under which the London schools labor is the greater difficulty of obtaining a doctor's degree (M.D.) in the metropolis than in the provinces and in Scotland and Ireland. In the latter localities nearly every medical school is attached to a university where the average student can obtain a degree. But in London there is only one university and the standard for its degree is the highest in Great Britain, much too high for the average student, who therefore contents himself with obtaining a license to practice from the Colleges of Physicians and Surgeons (L.R.C.P., M.R.C.S.). Though the license of the colleges confers the same right to practice as does a degree, the latter gives the physician a better status and alone entitles the holder to be called "doctor." But this title is indiscriminately applied to all who practice medicine by the majority of people. However, the holder of a license is placed at some disadvantage, especially among patients of the wealthier class. The difficulty of obtaining the doctor's degree has long been a grievance with the London medical schools, and attempts have been made to overcome it without success. The London University has been approached with a view to modifying its standard so as to render its degree more accessible to the bulk of the London students, but the university authorities and the alumni naturally object to a course which would lower the prestige of their degrees, which is now regarded as the foremost in the kingdom. The consequence of the comparative difficulty of obtaining a medical degree in London is that students are going in large numbers to the provincial schools, where for the same expenditure of time and money as it takes to obtain a license in London a degree can be obtained, and the London schools are, in spite of their unrivaled opportunities for clinical teaching, being depleted.

Increase of Women Pharmacists

A noticeable feature of the inaugural meeting of the present session of the Pharmaceutical Society was the large attendance of women, showing that the sex is alive to the opportunities presented by pharmacy as a lucrative and suitable occupation. In recent years there has been a great increase in the number of female pharmacists. Thirty years ago scarcely any entered the profession. As dispensers they are being employed in hospitals and by physicians who dispense their own medicines. They are also employed by pharmacists, but they are kept in the background and seldom seen in the shop, for the public has a great prejudice against being served with drugs by girls. The scale of payment is sufficient to attract women into the profession.

VIENNA LETTER

(From Our Regular Correspondent)

Vienna, Oct. 5, 1909.

A New Trick of the Antivivisectionists

Certain classes of "nature-healers" and other groups of dubious affiliation have lately attempted to secure legislation against what they call "vivisection." A large number of physicians and surgeons have been taken unawares and prompted to sign a harmless-looking leaflet, in which "unnecessary cruelty toward animals in experiments" was deprecated. Once the names and signatures were obtained, they were used to convince the public that even medical men themselves have come to believe that "vivisection" can be dispensed with without stopping the progress of science. Much mischief has been done by this misleading use of medical opinions. The "committee" which is responsible for the agitation remains quite anonymous. Thus the protests from those who want to disclaim the use of their names in this way cannot be addressed to any person. Medical councils have warned their members of the risk they run if they reply imprudently to such an invitation. A careful study of the replies given by medical men shows that not a single one is averse to experimental pathology, if conducted by proper men in a proper manner, with an anesthetic. The movement urges the passage of a bill in which each animal experiment should be made subject to a special written permission to be granted by a joint committee, to consist of an equal number of "experts" (not otherwise defined) and of members of the associations for protection of animals from cruelty. Needless to say, such a law would mean the extinction of that enormously important branch of medical research without which modern scientific work is impossible. As permission for the experiment would be given only with the understanding that the animal must be killed (by chloroform) after the end of the experiment, such proceedings would be simply useless for medicine. There is little probability that the bill will really be brought before parliament within the next few years, as our legislative fathers have very important political matters on their hands. But still the profession, and the teaching staff of the universities have seen enough of the animosity against education, so strong in the present ruling party, not to be quite free from anxiety.

The Overproduction of Medical Privat-Docents

The number of privat-docents in Austria has increased so rapidly that if the privat-docents of theoretical subjects are counted as well as others, at present there are in Vienna no less than 300 amongst 3,000 medical men in this city, or 10 per cent. This would be of little consequence if the "privat-docents" were such only for teaching purposes. But as a rule this title is aimed at solely for the purpose of commanding a better fee for medical advice, as the majority of our public are very fond of titles. They esteem a privat-docent or a professor of any small special branch more than an experienced mere practitioner, however superior the knowledge of the latter may be to that of the former. The title of "privat-docent" may be obtained by an assistant who does a few scientific researches and writes a good deal about his specialty. Several university men have raised objections both to the "proletarization," as they termed it, of the teaching staff, and to the misuse of this title in medical practice. It has been suggested for instance that the use of the title "privat-docent" should not be allowed on the door-plate or visiting-card or the prescription, but only in connection with university work and in literature. This title should be granted under severer restrictions, and only in recognition of really important scientific contributions.

The Coming Winter Term of the Vienna Medical School

The great majority of the lectures and classes of the Vienna medical school will take place, as usual, in the Allegemeines Krankenhaus and the Poliklinik, the remainder in the smaller hospitals. Twenty-nine ordinary, 67 extraordinary professors, 170 privat-docents have announced their classes. There will be 97 classes in internal medicine, 49 in surgery, 43 in gynecology and obstetrics, 39 in pathology and morbid anatomy; 38 classes will deal with dermatology, including syphilis; ophthalmology has 32 classes, otology 27, psychiatry 23, anatomy 18, pediatrics 17, chemistry 15, forensic medicine 14, rhinolaryngology 14, materia medica 13. Altogether, 457 classes, against 445 in the last winter-term, will be held this year. This does not include the classes which are repeated because an excessive number of students apply for them. These parallel classes increase the number by about 10 per cent.

BERLIN LETTER

(From Our Regular Correspondent)

Berlin, Oct. 6, 1909.

Prizes Offered by the German Central Committee for Cancer Research

The management of the German central committee for cancer research has offered prizes on the somewhat strange assumption that the general practitioner needs further instruction in the early clinical diagnosis of carcinoma. These prizes are to be awarded for an exposition of the early diagnosis of cancer as brief as possible, but covering the entire field, which shall be suitable for distribution as a pamphlet to practicing physicians. Three prizes are offered of $250, $125 and $75 (1,000 500 and 300 marks). The competition is open to every physician in Germany.

Comparative Mortality in England and Germany

On the basis of the latest published German mortality tables for 1891 to 1900 and the mortality table for England published in 1907 and covering the same period, the well-known medical statistician, Dr. Prinzing, publishes investigations in the last number of *Soziale Medizin und Hygiene*, which yield the following interesting results:

The mortality in England and Germany for the last decade for the ages of from 2 to 30 has materially diminished. The mortality of infants, which was formerly already smaller in England than in Germany, is still at the present time much more favorable, especially in the period of early infancy and at the ages of from 6 to 11 years. The lower mortality of the latter life period in England, depends for the most part on the fact that for decades diphtheria in England has been much less widespread than in Germany. In adult life, on the other hand, the mortality in Germany has diminished more than in England, so that to-day the male sex of ages from 28 to 66 years and the female of ages 37 to 62 years show relatively a smaller mortality in Germany than in England, although three decades ago this was true only for short life periods. It may safely be assumed for Germany that the more favorable showing of the mortality in the life period of the greatest earning power is to be attributed, in addition to the increase of the general welfare and the improvement of housing conditions, to the extended social precautions and the system of compulsory insurance. The reason for the higher mortality in England in this period of life is the predominant urban character of the English population. The mortality after the sixtieth year has been considerably reduced in Germany, while it has risen in England. It is, to be sure, still lower in old age in England than in Germany, but the difference has notably decreased. Although the evolution of the mortality in Germany affords reason for considerable satisfaction, still marked progress must yet be made for the mortality in infancy, at the age of from 6 to 10 years, in young men from 17 to 21, and women from 20 to 30, to reach the low figure which it has already reached in England.

Meeting of the German Scientific Association

The annual meeting of the association of German scientists and physicians (*Gesellschaft deutscher Naturforscher und Aerzte*), which closed a few days ago, had to its credit only a relatively small number of important contributions. One important reason for this was naturally the occurrence of the international congress at Budapest only two weeks previously, which had attracted a number of German physicians. This circumstance also shows again the unfavorable result of the undue frequency of congresses. The scientific output of the naturalist section was also unimportant. Only the special congresses that meet as sections of the scientific association—the German pediatric society, the German pathologic society and the medicolegal society were able to show a somewhat extensive program. The meeting for next year will be held at Königsberg.

Chronicle for Berlin University for 1908

Some interesting data are furnished from the announcement of our university which has just appeared. Six thousand two hundred and nine students were matriculated in the summer semester of 1908. Of these, 909 were medical students, but to these are to be added 366 students of the Kaiser Wilhelm army medical school. In the medical school were 321 foreign students. In the winter semester of 1908 and 1909 the number of students was 7,869 men and 409 women. The number is, as may be seen, greater than in the summer, because at that season the South German universities are attended to a greater extent. There were 1,224 men and 88 women medical students, and in addition, 377 students of the Kaiser Wilhelm Academy. Seventy-nine were graduated as doctors of medicine in the entire year; 10 were admitted to the faculty as privat docents in medicine.

Pharmacology

THE PURITY OF COMMERCIAL BILE SALTS

J. H. Long, M.S., Sc.D., and W. A. Johnson, Ph.C.

On account of the increased interest in the physiologic behavior of the bile salts and acids a number of these preparations in purified form have appeared in the market. It has been thought desirable to make a rather complete examination of some of the best known of these products, and the results obtained in this work are given below. The substances analyzed were all secured from the manufacturers by the secretary of the Council on Pharmacy and Chemistry.

It requires but a very superficial examination to show that these salts, as now sold, in some cases at least, are very different from the old gummy products obtainable a few years ago. The initial step in the separation of the salts from the bile is doubtless that followed in the production of the "crystallized bile" of Plattner, that is, precipitation of the alcoholic solution of the evaporated bile by an excess of ether. This treatment throws out the alkali salts of the bile acids. The further treatment evidently varies with the different manufacturers, and leads to products with different degrees of purity. The following tests have been made:

BILE SALTS (FAIRCHILD BROTHERS & FOSTER)

This is a dry and very nearly white powder of crystalline appearance under the microscope. It dissolves readily in water, giving a yellowish solution. We found on analysis:

		For Dry Subst.
Moisture	1.67 per cent.	
Ash	8.85 per cent.	9.01 per cent.
Nitrogen	2.57 per cent.	2.61 per cent.
Sulphur	3.70 per cent.	3.76 per cent.
Phosphoric anhyd.	1.10 per cent.	1.12 per cent.
Specific rotation	20.9°	21.3° for c = 5

A word must be said about some of these determinations. The ash as here reported is the residue left after incineration and prolonged heating over the blast lamp. Sodium taurocholate leaves an acid ash containing acid sodium sulphate, which becomes the ordinary sulphate on strong ignition. The glycocholate leaves an alkaline ash containing carbonate, and the two salts heated together would increase the yield of sulphate through the added alkali from the glycocholate. The ash of the taurocholate, after prolonged fusion, should amount to about 13.2 per cent. and the sulphur to 5.95 per cent. Our results suggest a mixture, but the sulphur and ash determinations can not be calculated to a mixture of the two principal salts, the glycocholate and taurocholate. The difficulty is partly accounted for by the presence of phosphorus in the ash, which appears in relatively large amount. So far as known none of the bile salts contains phosphorus, but another constituent of the bile, usually overlooked, holds phosphorus in marked quantity. This is a lecithin, and it has been shown that in the preparation of the bile salts this phosphatid clings tenaciously. Hammarsten refers to the presence of the phosphorus in bile salts as probably due to a lecithin, and the matter has been rather fully investigated in this laboratory by one of us and Gephart.,[1] who prepared and purified a bile salt which on analysis gave these figures:

N	2.64 per cent.
S	3.70 per cent.
P_2O_5	0.66 per cent.

It was found by these authors that a given weight of bile salts will carry down a much greater weight of lecithin than is indicated by these figures. A second salt prepared in the laboratory showed on analysis:

N	2.43 per cent.
P_2O_5	0.87 per cent.

When this salt was mixed with egg lecithin in the proportion of 5 parts of the first to 3.95 of the other, taken up with alcohol and precipitated by ether, a mixture was secured which gave as follows:

N	2.24 per cent.
P_2O_5	3.94 per cent.

How the lecithin is held in such mixtures, of which many were made, can not be stated, but it is not removable by ether washing. In view of these facts we must look on this bile salt as a normal one containing from 12 to 13 per cent. of a lecithin body, or similar phosphorus-holding complex. Assuming this to be the common monamino monophosphatid, the above figures may be approximately duplicated by a mixture of salts and lecithin as follows:

	Per Cent.	S	N	P_2O_5
Lecithin	12.5	0.00	0.22	1.10
Sodium taurocholate	63.5	3.78	1.65	
Sodium glycocholate	24.0	0.00	.69	
		3.78	2.56	1.10

The relatively low ash of the preparation examined, and the high specific rotation are well accounted for by such a mixture as the above. In many other salt mixtures which we have examined the ratio of the taurocholate to the glycocholate is about the same as here indicated, as ox-bile is the common material worked up.

BILE SALTS (ABBOTT ALKALOIDAL COMPANY)

This preparation is not as light as the one just described. It is brownish yellow, and dissolves in water to which it imparts considerable color. On this account much difficulty was found in purifying a solution sufficiently to permit a satisfactory determination of the specific rotation. This was finally accomplished by long treatment with animal charcoal, without loss of the substance itself. Analysis gave:

		For Dry Subst.
Moisture	3.15 per cent.	
Ash	8.44 per cent.	8.71 per cent.
Nitrogen	2.44 per cent.	2.52 per cent.
Sulphur	3.95 per cent.	4.08 per cent.
Phosphoric anhyd.	1.82 per cent.	1.88 per cent.
Specific rotation	18.3°	18.9° for c = 5

It is evident from these figures that the percentage of taurocholate is a little higher in this sample than in the last one. The most marked peculiarity, however, is in the much higher phosphorus content. The nitrogen and the specific rotation are correspondingly low. Phosphatids like lecithin are gummy substances, but the combinations with the bile salts are hard solids. It is possible that the phosphorus may be held wholly in such a combination, in which case the above figures correspond closely to a mixture like the following:

	Per Cent.	S	N	P_2O_5
Lecithin	21	0.00	0.36	1.85
Sodium taurocholate	68	4.05	1.77	
Sodium glycocholate	11	0.00	.32	
		4.05	2.45	

---

[1] Jour. Am. Chem. Soc., August, 1908, where the literature is quoted.

A mixture in these proportions would give a specific rotation of 19.3°, while we found 18.9°. In this calculation Ulpiana's value for lecithin is used, which possibly is high.

This salt is apparently likewise a normal product from the bile, notwithstanding the high phosphorus content. Our knowledge as to the nature of the bile-salt and lecithin combination is as yet too imperfect to warrant any very definite opinion as to the average composition of the mixture precipitated by ether. The amount of phosphorus given here is not as large as in some of the analyses reported in the work of Hammarsten, referred to above.

SODIUM TAUROCHOLATE (MERCK & COMPANY)

In some biles this salt is relatively abundant, and the separation is not considered difficult. In the case before us, however, the separation and purification have been far from satisfactory, as the analytical figures show. They are as follows:

		For Dry Subst.
Moisture	2.87 per cent.	
Ash	13.60 per cent.	14.00 per cent.
Nitrogen	0.97 per cent.	1.00 per cent.
Sulphur	1.68 per cent.	1.73 per cent.
Phosphoric anhyd. ..	trace per cent.	trace per cent.
Specific rotation ...	16.0°	16.4°

On ignition of the salt over the Bunsen burner the white ash secured amounted to about 19 per cent. of the whole. This over the blast lamp was reduced to the value given, which behavior, taken alone, is somewhat suggestive of the taurocholate. But the very low nitrogen, low sulphur and low specific rotation indicate, apparently, a decomposition product. The salt dissolves, giving a solution with a very dark color and a bad odor. It is possible that in the attempt at purification some cholate was formed with loss of a corresponding amount of taurocholate. The analytical results are best explained in this way, but the rotation should be higher in such case. No effort was made to follow the matter further. The product is evidently not what it is labeled.

SODIUM GLYCOCHOLATE (MERCK & COMPANY)

This salt appears to be even more contaminated with foreign substances than is the preceding one. The water solution secured was very dark and the odor bad. The purification for the specific rotation determination was unusually difficult. The following results were obtained on analysis, and here, as in all the other cases, duplicate tests were made. The nitrogen and sulphur determinations were repeated by a second analyst, with very close agreement.

		For Dry Subst.
Moisture	1.69 per cent.	
Ash	12.85 per cent.	13.07 per cent.
Nitrogen	0.53 per cent.	0.54 per cent.
Sulphur	0.84 per cent.	0.86 per cent.
Phosphoric anhyd. ..	trace per cent.	trace per cent.
Specific rotation	14.0°	14.2°

It will be observed that the phosphorus is low in both of these salts, which further goes to show profound alteration from the normal condition. It is not possible to account for the decomposition here indicated, but it will be noticed that the nitrogen is decreased as well as the sulphur. The optical rotation is only about two-thirds of the normal.

COLALIN (RUFUS CROWELL & COMPANY).

This product has been described as hyocholalic acid, and as such should contain no nitrogen. According to the manufacturers, it is made by the process of Jolin, as described in vol. xiii, of the *Zeitschrift für physiologische Chemie*, which, if properly carried out, should furnish a nitrogen-free product. The following results show the actual situation, as found by our recent analyses:

		For Dry Subst.
Moisture	3.80 per cent.	
Ash	2.00 per cent.	2.08 per cent.
Nitrogen	2.90 per cent.	3.01 per cent.
Sulphur	0.60 per cent.	0.62 per cent.
Phosphoric anhyd. ..	trace per cent.	trace per cent.
Specific rotation	5.48°	5.69°

The ash is not present as a residue from the alkali salts of the bile, but is practically all in insoluble form. According to the manufacturer, it is magnesia, added to prevent the caking of the product; our tests agree with this statement. The sulphur points to the presence of taurocholic acid, not fully separated from the glycocholic acid by the original process. The very high nitrogen content is interesting; for pure glycocholic acid this should amount to 3.01 per cent., and for hyoglycocholic acid, which, according to Jolin and others who have worked on the problem, has a slightly different composition, the nitrogen content is 3.04 per cent. Counting out the magnesia, the results found by us would approximate to this value very closely. The small content of taurocholate, suggested by the sulphur, would not lower the nitrogen value appreciably.

The data for the optical rotation of hyoglycocholic acid are not very definite, and different values seem to belong to the two forms, the alpha and beta varieties, said to be present in hog bile. Our value was obtained from the alcoholic solution after a rather lengthy purification process, which was possibly attended with some loss. Jolin gives the value for the alpha form of hyoglycocholic acid as + 9.7°, and states that for the other form the rotation is lower. For hyocholalic acid he gives + 5.9°.

If it were not for the presence of the large amount of nitrogen our rotation would suggest this acid, as the preparation is claimed to be. The rotation of the acid from ox-bile is much higher than from the bile of the hog, and in this respect our results point to the latter as the original source in the manufacture.

Taking all things into consideration, it is evident that the product is probably a mixture of hyoglycocholic and hyotaurocholic acids, rather than the corresponding cholalic acids, as the manufacturer assumes it to be. A revision of the description is evidently called for. It should be added that the nitrogen is not present as an ammonium or other soluble salt, nor in a protein combination. Both nitrogen and sulphur are present in forms insoluble in water, but soluble in alcohol, and are evidently a part of the acid molecule.

A Correction

Among the reports issued by the President's Homes Commission (Senate Document No. 644) was one by the Committee on Social Betterment which contained a chapter on "The Drug Habit." In this chapter was a list, furnished the committee by the Department of Agriculture, of "patent medicines," containing habit-forming drugs, among which was "Fruit-Lax," alleged to contain morphin. This list was reproduced in THE JOURNAL, May 29, 1909. Now we are informed that this particular preparation—"Fruit-Lax"—was included in the list furnished the committee and published in Senate Document No. 644, through a clerical error, since there was no reason to suppose that it contained morphin.

Seizure of Waterbury's Metabolized Cod-Liver Oil Compound

On two occasions[1] THE JOURNAL has shown the falsity of the claims made for Waterbury's Metabolized Cod-Liver Oil Compound. As recently as October 9 it was demonstrated that the product contains salicylic acid, and "does not deserve to be designated as a cod-liver oil preparation," as the amount of fatty acids it contains is not more than one part in a thousand. It is interesting to note in this connection that the United States Government has now seized a consignment of this product on the ground that it is misbranded. The reasons given for the government's action are that:

> " . . . the labels bear certain statements regarding said drug which are exaggerated, false and misleading and that among the said exaggerated, false and misleading statements are the following, that is to say: 'Waterbury's Metabolized Cod-Liver Oil. This product contains the metabolized product obtained by the action of ferments on cod-liver oil;' and the further statement: 'Waterbury's Metabolized Cod-Liver Oil Compound does contain cod-liver oil;' and the further statement that many institutions are using it exclusively as the one general tonic and tissue builder; and the further statement that 'blue wrapper indicates product without antiseptic' . . ."
>
> "These statements and all of them are exaggerated, false and misleading in this, that said product obtained contains no material

---

[1] Oct. 13, 1906, and Oct. 9, 1909.

part derived from cod-liver oil, due to metabolic changes; and further, that said product contains no cod-liver oil; and further, that said product is not such that is could be a tissue builder, and that it is not a tissue builder; and further, that said product contained in the bottles wrapped as aforesaid in the blue wrapper contains a product which is an antiseptic, that is to say, contains salicylic acid, and that these statements heretofore enumerated, and all of them, regarding said liquor or drug are exaggerated, false and misleading . . ."

The manufacturer will have thirty days in which to reply to the charges brought by the government and to show cause why the product should not be condemned and confiscated.

Correspondence

Hygiene of Childhood

To the Editor:—On the invitation of the Department of State of the United States Government, the Fifteenth International Congress on Hygiene and Demography will convene for the first time on the American continent in Washington, D. C., Sept. 26 to Oct. 1, 1910. Section III of this congress deals with the subjects of the "Hygiene of Infancy and Childhood: School Hygiene." It is believed that this will be a meeting of the utmost importance. We take this means of requesting your readers to let us know [at 1 Madison av., New York City] of any pieces of original work which are being done, bearing on this topic.

A. Jacobi, President.
Luther H. Gulick, Secretary.

The Investigation of Blood for Tubercle Bacilli

To the Editor:—In a letter in The Journal (Oct. 2, 1909, liii, 1113), Burnham claims "priority" for Burnham and Lyons *apropos* of the work published by me in The Journal (Sept. 18, 1909, liii, 909), in which I found distilled water contaminated with acid-fast bacilli. Burnham and Lyons found vibrios contaminating their water while they were searching for typhoid bacilli in fresh blood, but they did not find acid-fast organisms in the water. In one of their preparations, made with blood from the lobe of the ear, they found tubercle-like bacilli which they considered contaminating organisms from ear wax. Apparently, it did not occur to them that these might have come from distilled water.

It does not seem to me that their experience was similar to mine, as Burnham's letter states, or that Burnham is justified in his claim. Their work was published in the *New Orleans Medical and Surgical Journal*, October, 1909.

Walter Brem, M.D., Colon Hospital, Cristobal, C. Z.

Miscellany

Impressions of America.—Professor Hofmeier devotes twelve pages in the *Zeitschrift für Geburtshülfe und Gynäkologie*, lxv, p. 242, to an account of a trip through the United States last spring. He was the representative of Germany at the centennial of the first ovariotomy, celebrated by the American Gynecologic Society, and deplores the earliness of the date, which left an interval of six weeks before the session of the American Medical Association, so that he was unable to attend the latter. In commenting on the limitation of membership to 100, he remarks that this must shut out a large number of the younger physicians from the work in this scientific society, and the latter loses the inspiration from young enthusiasm which in Germany is found so useful. He slyly adds that this is a striking example of the democratic conception of freedom and equality in America. "With all its external democratic form it does not exclude a far-reaching social exclusiveness." He also comments on the difference between American and German gynecology; the American gynecologists do abdominal surgery in the widest sense of the term, and not on women alone, while many cut out obstetrics altogether. The society loses, he thinks, by excluding the anatomic, bacteriologic, embryologic and obstetric questions to which the German society pays so much attention. Clinical instruction in obstetrics seems to him rather backward here, which he ascribes to the disinclination of American women to go to a maternity; only 949 of the 6,274 patients in the Lying-in Hospital of New York in 1908 were American born. The lack of reciprocity between the different states impressed him as very strange, as also the enthusiasm for athletics, but he adds that German students might well learn from Americans that it is possible to enjoy their youth without pouring a couple of quarts of beer into their stomach every day. American academic athletics must encroach, he thinks, on the scientific work, but it would be a great gain in Germany if more in this line could be fostered at the expense of the time spent by students in the saloons, the *Kneipenleben*. In conclusion he speaks rather wistfully of the way in which the Germans residing here are fast becoming Americanized. They maintain their national characteristics nearly unmodified in Slavonic, oriental and Latin countries, but they soon blend with Anglo-Saxon civilization.

Infant Mortality.—The problem of infant mortality must be solved in the tenements. By reason of large numbers and gross ignorance the vast majority of deaths occur here. There are many factors which enter into the problem. The milk supply of New York City has been decidedly improved during the last few years, and it is questionable whether a still further improvement which under present conditions would be difficult and expensive, would be followed by a marked lowering of the death rate. The questions of poverty, poor housing, alcoholism, cannot be materially influenced within a few years. What can be done now? It is a significant fact that the infant mortality is highest in those countries in which illiteracy among the women is greatest. The colossal ignorance of the poor on questions of infant feeding and hygiene can be immediately dealt with. Aside from economic and humanitarian considerations the health authorities and physicians are in duty bound to see to it that there is no needless waste of human life. In no department of medicine are proper measures more likely to be followed by rapid and striking results than in the reduction of the infant mortality.—C. Herrman, in *Pediatrics*.

Free Information on Hygiene.—Dr. Irving Fisher says that just as the Department of Agriculture supplies specific information to the farmer concerning the raising of crops or live stock, so another department, devoted perhaps, to health and education, should be prepared to provide every health officer, school teacher, employer, physician and private family with specific information in regard to hygiene.

Queries and Minor Notes

Anonymous Communications will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

INTRAVENOUS INJECTION OF MERCURY SUCCINIMID

To the Editor:—Please answer the following queries:

1. Is it possible to inject mercury succinimid by the intravenous method without harmful effect, and if so, in what dosage?

2. Are mercury and arsenic preparations incompatible when used in the same solution or, if given intramuscularly, at the same time?

3. Could novocain be used with mercury succinimid to deaden the pain of injection?

H. Smith, Los Angeles, Cal.

Answer.—1. There appears to be no reason why mercury succinimid should not be used in the same dosage as other soluble salts of mercury for intravenous injection. The dose recommended is from 2 to 3 c.c. of a 1 per cent. solution, injected once in two or three days.

2. The arsenious preparations, such as salts of arsenious acid and trioxid of arsenic, are reducing agents and hence incompatible with the mercuric salts, which they reduce to insoluble mercurous compounds or to metallic mercury. The arsenates of mercury are insoluble and therefore salts of arsenic acid are incompatible with the mercuric salts. It is stated that atoxyl (sodium arsanilate) is incompatible with compounds of mercury. The reason for this is not certainly known. If a solution of an arsenious compound, and a solution of a mercuric compound are injected separately, the chemical reasons for incompatibility would probably not be valid,

except that if reduction of the mercury compound should occur the mercury might not be so quickly absorbed.

3. As the text-books do not answer this question, it was submitted to the Chemical Laboratory of the Association for Investigation. The report of the laboratory is as follows: "Solutions of mercury succinimid and novocain were prepared separately and mixed, and the mixture allowed to stand over night. No reaction was observed. Hence, there would seem to be no reason why novocain cannot be used with mercury succinimid to deaden the pain of injection."

VASECTOMY AND CASTRATION OF CRIMINALS AND DEFECTIVES

To the Editor:—Please give a bibliography of the more important literature in English on vasectomy and castration of criminals, idiots, insane, etc. J. A. Burnett, Chismville, Ark.

Answer.—Ewell, J.: "Plea for Castration to Prevent Criminal Assault," *Virginia Med. Semi-Monthly*, Jan. 11, 1907.

Belfield, W. T.: "Race Suicide for Social Parasites," The Journal A. M. A., Jan. 4, 1908, l, 55.

"Vasectomy for Confirmed Criminals and Defectives," editorial in The Journal A. M. A., April 3, 1909, lii, 1114.

Belfield, W. T.: "Sterilization of Criminals and Other Defectives by Vasectomy," *Chicago Med. Recorder*, March, 1909; abstr. in The Journal A. M. A., April 10, 1909, lii, 1211.

"The Sterilization of Defectives," a monograph published by H. C. Sharp, Jeffersonville, Ind.

The Public Service

Medical Department of the Army

Changes for the week ended Oct. 16, 1909:

Havard, Valery, colonel, granted leave of absence for three months, twenty-three days.

Woodbury, Frank T., capt., granted leave of absence for two months.

Byrne, Charles B., colonel, granted leave of absence for two months, twenty days.

Hains, Edgar F., 1st lieut., M. R. C., ordered to active duty; will proceed to Fort Moultrie, S. C., for duty.

Hull, Alva R., 1st lieut., M. R. C., granted an extension of fifteen days to his leave of absence.

Wiggin, Dayton C., 1st lieut., M. R. C., granted leave of absence for one month.

Leeper, John F., 1st lieut., M. R. C., relieved from duty at the Army General Hospital, Fort Bayard, N. M., and ordered to Fort Duchesne, Utah, for duty.

Van Kirk, Harry H., 1st lieut., M. R. C., relieved from duty at Fort Duchesne, Utah, and ordered to Fort Levett, Maine, for duty.

Scott, Minot E., D. S., ordered to proceed from South Berkeley, Cal., to Vancouver Barracks, Washington, for duty.

Gunckel, George I., D. S., left Fort Oglethorpe, Ga., for duty at Fort McPherson, Ga.

Ames, John R., D.S., left Fort Lincoln, N. Dak., for duty at Fort Assinniboine, Mont.

Medical Corps of the Navy

Changes for the week ended Oct. 16, 1909:

Fitzsimons, P., medical director, detached from command of the Naval Medical Supply Depot, New York, N. Y., and ordered to Washington, D. C., for duty as a member of the Naval Retiring Board.

Dickinson, D., medical director, detached from duty as a member of the Naval Retiring Board, Naval Examining, and Naval Medical Examining Boards, Washington, D. C., and ordered home to wait orders.

DuBose, W. R., medical inspector, detached from the Bureau of Medicine and Surgery, Navy Department, and ordered home to wait orders.

Lovering, detached from the Naval Hospital, Norfolk, Va., and ordered to command the Naval Medical Supply Depot, New York.

Holeman, C. J., asst.-surgeon, detached from the *Arethusa* and ordered to duty in connection with the *Iris* and to duty on board that vessel when commissioned.

DuBose, W. R., medical inspector, ordered to command the Naval Hospital, Norfolk, Va.

Casto, D. H., asst.-surgeon, detached from the *Concord* and ordered to duty in connection with the fitting out of the *Princeton* and to duty on board that vessel when commissioned.

Gardner, J. E., medical inspector, detached from the Naval Recruiting Station, Boston, and ordered to continue other duties.

Wilson, H. D., surgeon, unexpired portion of leave revoked; ordered to the Naval Recruiting Station, Boston.

Strite, C. E., asst.-surgeon, unexpired portion of leave revoked; detached from the Naval Recruiting Station, Baltimore, and ordered to the *Franklin*.

Public Health and Marine-Hospital Service

List of changes for the week ended Oct. 13, 1909:

Trask, J. W., asst.-surgeon-general, Anderson, John F., P .A. surgeon, detailed to represent the Service at the annual meeting of the American Public Health Association, to be held in Richmond, Va., Oct. 19-21, 1909.

White, J. H., surgeon, directed to proceed to Galveston, Tex., on special temporary duty.

Fager, J. M., surgeon, granted 1 day's leave of absence, Oct. 17, 1909.

Oakley, J. H., surgeon, granted 1 day's leave of absence, Oct. 12, 1909.

Lavinder, C. H., P. A. surgeon, bureau order of Sept. 22, 1909, amended to read on completion of duty enjoined, directed to proceed to Jackson, La., on special temporary duty.

Moors, Dunlop, P. A. surgeon, directed to report to the medical officer in command at San Francisco, for temporary duty and assignment to quarters.

Francis, Edward, P. A. surgeon, on being relieved by Passed Assistant Surgeon Hugh de Valin, directed to proceed to Washington, D. C., and report to the Director of the Hygienic Laboratory for duty.

Boggess, J. S., P. A. surgeon, granted 3 months' leave of absence from Oct. 15, 1909.

Sweet, Ernest A., P. A. surgeon, relieved from duty at Ellis Island, N. Y., and directed to proceed to Stapleton, N. Y., and report to the medical officer in command for duty and assignment to quarters.

Ashford, F. A., P. A. surgeon, on arrival of Passed Assistant Surgeon Ernest A. Sweet, relieved from duty at Stapleton, N. Y., and directed to proceed to Ellis Island, N. Y., and report to the Chief Medical Officer for duty.

De Valin, Hugh, P. A. surgeon, on being relieved by Assistant Surgeon Charles M. Fauntleroy, directed to proceed to the Mobile Quarantine Station and assume command of the Service.

Krulish, Emil, asst.-surgeon, granted 10 days' leave of absence from Oct. 15, 1909.

Fauntleroy, Charles M., asst.-surgeon, on the arrival of Assistant Surgeon R. H. Lyon, directed to proceed to Savannah Quarantine Station, Ga., and assume command of the Service.

Lyon, R .H., asst.-surgeon, relieved from duty at Reedy Island Quarantine Station, and directed to proceed to New Orleans Quarantine Station, and report to the medical officer in command for duty and assignment to quarters.

Gustetter, A. L., acting asst.-surgeon, granted 5 days' leave of absence from Oct. 13, 1909.

Hallett, E. B., acting asst.-surgeon, granted 7 days' leave of absence from Oct. 12, 1909.

Hume, Lea, acting asst.-surgeon, granted 10 days' leave of absence from Oct. 10, 1909.

Lowthian, E. L., acting asst.-surgeon, granted 27 days' leave of absence from Oct. 4, 1909.

BOARD CONVENED

Board of medical officers convened to meet at Seattle, Wash., Oct. 6 and 7, 1909, for the purpose of examining an alien. Detail for the board: Passed Assistant Surgeon M. W. Glover, chairman; Assistant Surgeon C. W. Chapin; Acting Assistant Surgeon F. R. Underwood, recorder.

Health Reports

The following have been reported to the Public Health and Marine-Hospital Service, during the week ended Oct. 15, 1909:

SMALLPOX—UNITED STATES

District of Columbia: Washington, Sept. 25-Oct. 2, 2 cases.
Massachusetts: Boston, Sept. 25-Oct. 2, 1 case.
Minnesota: Duluth, Sept. 17-24, 1 case.
Missouri: St. Louis, Sept. 25-Oct. 2, 1 case.
Montana: Butte, Sept. 23-30, 3 cases.
New Jersey: Newark, Sept. 18-25, 1 case.
North Carolina: Charlotte, Sept. 24-Oct. 1, 2 cases.
Ohio: Dayton, Sept. 25-Oct. 2, 2 cases.
Wisconsin: Milwaukee, Sept. 25-Oct. 2, 1 case.

SMALLPOX—FOREIGN

Brazil: Rio de Janeiro, Aug. 23-Sept. 12, 6 cases, 2 deaths.
China: Shanghai, Sept. 1-7, 1 case, on *U. S. S. Wilmington.*
Egypt, general, Aug. 12-19, 101 cases, 16 deaths; Cario, Sept. 2-9, 1 case, 2 deaths.
France: Bordeaux, Aug. 27-Sept. 4, 1 death; Paris, Sept. 11-18, 1 case.
Germany: Konigsberg, Aug. 22-28, 1 case, 1 death.
India: Bombay, Sept. 1-7, 1 death; Madras, Aug. 28-Sept. 3, 2 cases.
Indo-China: Saigon, July 31-Aug. 7, 1 case, 1 death.
Italy, general, Sept. 12-19, 9 cases; Naples, 10 cases, 2 deaths.
Mexico: Monterey, Sept. 19-26, 1 death.
Russia: Moscow, Sept. 4-11, 3 cases, 2 deaths; Odessa, Sept. 4-18, 17 cases, 3 deaths; Riga, Sept. 11-18, 2 cases; St. Petersburg, Sept. 4-11, 8 cases, 6 deaths; Warsaw, Aug. 7-14, 1 death.
Spain: Barcelona, Sept. 13-27, 5 deaths; Valencia, Sept. 11-18, 1 case; Vigo, 2 deaths.
Uruguay: Montevideo, July 1-31, 6 cases.

YELLOW FEVER

Ecuador: Guayaquil, Aug. 27-Sept. 11, 4 deaths.
Mexico: Merida, Sept. 28-Oct. 1, 1 case, 1 death; Tekik, Oct. 1, 1 case.

CHOLERA

China: Chefoo, Sept. 15, present.
Germany: Russ, Sept. 19, 1 case, 1 death, vicinity; Stolzenhagen, Sept. 18, 1 case.
India: Bombay, Sept. 1-7, 27 deaths; Rangoon, Aug. 21-28, 4 deaths.
Japan: Nagasaki, Sept. 9, 7 cases, 1 death, from *S. S. Taim Maru.*
Korea: Chemulpo, Sept. 15, present.
Netherlands: Halsteren, Sept. 1-7, 1 case; Hoogvliet, 1 case; Pernis, 1 case.
Russia: Moscow, Sept. 4-11, 3 cases, 1 death.
Straits Settlements: Singapore, Aug. 21-28, 1 death.
Sumatra: Djambi, July 1-31, 205 cases, 108 deaths.

PLAGUE—INSULAR

Hawaii: Hilo, Sept. 4-11, 1 case, 1 death.

PLAGUE—FOREIGN

Ecuador: Guayaquil, Aug. 27-Sept. 11, 14 deaths.
India: Bombay, Sept. 1-7, 27 deaths; Rangoon, Aug. 21-28, 19 deaths.
Indo-China: Saigon, July 31-Aug. 21, 18 cases, 18 deaths.
Japan: Kobe, Sept. 15, epidemic present; Nagasaki, present in quarantine; Shimonoseki, present.
Mauritius, general, July 15-Aug. 5, 9 deaths.
Morocco: Casablanca, July 15-Sept. 17, 4 deaths.
Siam: Bangkok, Aug. 21-28, 9 cases, 9 deaths.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

Public Health Cooperation in Minnesota

A most commendable movement was inaugurated at the recent meeting of the Minnesota State Medical Association held at Winona on October 12-14, when on the second day of the meeting the afternoon session was practically devoted to a symposium on the cooperation of state forces in Minnesota medicine, the object of the discussion being to evolve ideas and methods whereby all of the forces which make for better public health could be correlated and united. The titles in the symposium were as follows: "The State Medical Society," Dr. E. L. Tuohy, Duluth; "The State Board of Medical Examiners," Dr. F. A. Knights, Minneapolis; "The State Board of Health," Dr. H. M. Bracken. St. Paul, secretary of the State Board of Health; "The State Board of Control in its Medical Relationships," Dr. A. C. Rogers, Faribault; "The University of Minnesota in its Medical Relationships," Dr. Charles Lyman Greene, St. Paul; "The Medical Press," Dr. W. A. Jones, Minneapolis, editor of the *Journal of the Minnesota State Medical Association and the Northwestern Lancet;* "The Lay Press," Mr. Charles H. Grasty, of the *St. Paul Journal.*

The papers read were suggestive and the discussion which followed was enthusiastic and interesting. A committee was appointed to devise ways and means of cooperation of all the health forces of the state. Minnesota is in a peculiarly fortunate position for undertaking such coordinate work, as the only medical college in the state is the Medical Department of the State University, while the State Board of Health, the State Board of Medical Examiners, the Board of Control (having supervision over all state institutions) and the State Medical Association are all working with the utmost harmony and mutual understanding. Under these favorable conditions and with the best men in the state interested in the work, there is no reason why Minnesota cannot lead in a movement for better and more effective work in public health lines.

Census Plans

Hon. E. Dana Durand, director of the United States Census, has promulgated instructions for securing transcripts of deaths in selected registration states and cities. These transcripts are obtained every month by the Census Bureau from city and state registrars in the registration area and form the basis of the mortality statistics prepared by the Division of Vital Statistics under the supervision of Chief Statistician Cressy L. Wilbur. The enforcement of these new regulations will make possible the compilation of the most scientific and trustworthy mortality statistics ever compiled in connection with the United States census. The new revised version of the classification of the causes of death, adopted at the Paris conference for the second decennial revision of the international classification will go into effect Jan. 1, 1910. The new United States standard death certificate which the Vital Statistics Section of the American Public Health Association is expected to adopt at the coming meeting at Richmond, Va., will also be used for reporting of deaths of the registration area after January 1.

In his communication to state registrars, Mr. Durand emphasizes the importance of the exact agreement between the number of deaths as compiled by the state officials and by the Census Bureau. For the purpose of preventing discrepancies a monthly check list showing the deaths by months and weeks is supplied to each state registrar. The importance of accuracy and promptness in making reports is emphasized. City registrars are requested to observe these instructions the same as state registrars. Mr. Durand states that a city registrar should have in his hands the certificate for every death that occurs before any disposition is made of the body. Imperfect certificates or unsatisfactory statements of the cause of death should not be accepted. The cooperation of all registration officials is requested in order that the value of mortality statistics in the United States may be improved. Special attention is called to the importance of accurate and complete reports for 1910 in order that the complete returns for this year may be used as a basis of comparison.

Dr. Wilbur, chief statistician of the Division of Vital Statistics, states that the opportunity of inaugurating the use of the revised classification for mortality statistics in the actual census year is of the greatest value. In accordance with the resolution of the international commission, an official version of the revised titles used in the classification is being prepared in each language represented at the conference. The English translation has been made by Dr. Wilbur, assisted by the other American representatives, and Dr. G. W. Knibbs, commonwealth statistician of Australia. As a result, exactly the same tabular list will be used by all English-speaking countries. The next session of the conference for the revision of the International classification will be held in Paris in 1919, unless other arangements are made. It is the hope of those interested in the advancement of American vital statistics that the third decennial conference may be called by the American government and may meet at Washington.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
Bowling Green, Kentucky

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Second Month—Fourth Weekly Meeting

Diseases of Cerebral Veins and Sinuses

Primary, Marantic, Thrombosis: Etiology.—Age, prolonged illness, cachexiæ. Symptoms.—Preceding disease, venous stasis, local edema, mental symptoms.

Secondary, Infective, Thrombosis: Etiology.—Middle-ear disease, fractures, infections in nose, mouth and pharynx, erysipelas, anthrax. Symptoms.—Preceding infection, local symptoms, brain symptoms, septicemia.

Cerebral Palsies of Children

Etiology: (a) Prenatal conditions, lack of development, prematurity, porencephalia; (b) accidents at birth, protracted labors, vertex and breech presentations, abuse of forceps; (c) postnatal causes, age, infectious disease, injuries.

Symptoms: Hemiplegic cases. Sudden onset, convulsions, loss of consciousness, development of hemiplegia, spasticity, exaggerated reflexes, contractures, attitude and gait. Atrophy of affected side. Athetosis. Tendency to epilepsy. Diplegic cases, may be paraplegic. Usually of prenatal or birth origin. Slow development of cranium, convulsive seizures, rigidity and contractions, upper and lower limbs involved. Lack of mental development, tendency to epilepsy and idiocy.

Monthly Meeting

Varieties of Aphasia and Significance of Each.
The Localization of the Lesion in Intracerebral Hemorrhage.
Early Diagnosis and Treatment of Cerebral Palsies of Children.

REFERENCE BOOKS FOR THE SECOND MONTH

Church and Peterson: Nervous and Mental Diseases.
Strümpell: Practice of Medicine.
Osler: Practice of Medicine.
Gowers: Brain and Crainal Nerves, vol. ii.
Mettler: Diseases of the Nervous System.
Sachs: Nervous Diseases of Children.

Nothing New Under the Sun.—It is curious to observe that the present scientific teaching on the basis of demonstrated fact is a return to a much earlier popular conception. Consumption was formerly popularly believed in some localities to be contagious. That belief rested on superficial observation, while the present teaching rests on demonstrated fact.—*Propaganda of the N. Y. State Charities Aid Association.*

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arkansas: Regular, Little Rock, November 9. Sec., Dr. F. T. Murphy, Brinkley.
Connecticut: Homeopathic, New Haven, November 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.
Connecticut: Regular, City Hall, New Haven, November 9-10. Sec., Dr. Charles A. Tuttle, 196 York St.
Florida: Jacksonville, November 10-11. Sec., Dr. J. D. Fernandez.
Louisiana: Homeopathic, New Orleans, November 1. Sec., Dr. Gayle Aiken, 1102 St. Charles Ave.
Maine: Portland, November 9-10. Sec., Dr. Frank W. Searle, 806 Congress St.
Massachusetts: State House, Boston, November 9-11. Sec., Dr. E. B. Harvey, Room 159, State House.
Nebraska: Senate Chamber, State House, Lincoln, November 10-11. Sec., Dr. E. Arthur Carr, 141 South Twelfth St.
Nevada: Carson City, November 1. Sec., Dr. S. L. Lee.
Texas: Levy Bldg., Greenville, November 9-11. Sec., Dr. M. E. Daniel, Honey Grove.
West Virginia: Chancellor Hotel, Parkersburg, November 9-11 Sec., Dr. H. A. Barbee, Point Pleasant.

Kentucky July Report

Dr. J. N. McCormack, secretary of the Kentucky State Board of Health, reports the written examination held at Louisville, July 6-8, 1909. The number of subjects examined in was 10; percentage required to pass, 70. The total number of candidates examined was 124, of whom 107 passed and 17 failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Bennett Medical College	(1908)	81
Northwestern University Medical School	(1909)	86
College of Physicians and Surgeons, Chicago	(1909)	78
University of Louisville (1908) 70, 70, 74, 75, 77, 84; (1909) the grades of 70, 71 and 72 were reached by one each; 73 by two; 74 by six; 75 by one; 76 by three; 77 by one; 78 and 80 by two each; 81 by three; 82 by five; 83 by six; 84 by eight; 85 by five; 86 by eight; 87 by one; 88 by four; 89 by five; 90 by seven; 91 by three and 93 by *one*.		
Kentucky School of Medicine (1891) 75;	(1898)	77

Marriages

Simon Wendkos, M.D., to Miss Sara Seidman, both of Philadelphia, October 10.

Frank R. Morley, M.D., to Miss Linnie B. Camp, both of Sedalia, Mo., October 1.

William A. Walters, M.D. Chicago, to Katherine Stull, M.D., of Auburn, Neb., October 6.

Rufus E. Fort, M.D., Nashville, Tenn., to Miss Louise Clark of Framingham, Mass., October 12.

Harry Joseph Sheffield, M.D., Narrowsburg, N. Y., to Miss Edna M. Cassebeer, October 1.

John Hunter Selby, M.D., Warrenton, Va., to Miss Delia Slaughter, at Warrenton, October 6.

William R. Marshall, M.D., Butler, Pa., to Miss Alma G. Bradley of Philadelphia, October 9.

Nathaniel Burwell, M.D., to Miss Loraine Turner, both of Shepherdstown, W. Va., October 7.

Nathaniel Thomas Ennett, M.D., to Miss Amy Conyers Tutwiler, both of Richmond, Va., October 6.

Clarence T. Lewis, M.D., to Mrs Van Pelt, both of Staunton, Va., at Washington, D. C., October 1.

Harold Roy Lucas, M.D., Chaffee, Mo., to Miss Mary May Neergaard of Springfield, Mo., September 13.

David T. Martyn, Jr., M.D., Columbus, Neb., to Miss Winnifred Rottger of Mt. Sterling, Ill., October 19.

Davenport White, M.D., New York City, to Miss Maude Cecelie Lambert of Washington, D. C., October 5.

Roy Ernest Leitz, M.D., Musselshell, Mont., to Miss Rosa Waters Ridgely of Washington, D. C., October 7.

John William Moore, M.D., Charleston, W. Va., to Miss Anna Estill Preston of Lexington, Va., October 6.

Chester Waterman, M.D., Central Islip, N. Y., to Miss Eleanor Alicia Atkinson of Yonkers, N. Y., October 6.

Thomas J. Nalley, M.D., St. Louis, to Mrs. Nellie Bradley of Seattle, Wash., at Minneapolis, Minn., October 1.

Frederick Tremaine Billings, M.D., Pittsburg, Pa., to Miss Romaine Le Moyne, at Garrison Forest, Md., October 6.

William Claiborne Powell, M.D., Petersburg, Va., to Miss Sara Breckenridge Early of Campbell county, Va., at Lynchburg, Va., October 5.

Deaths

Joseph P. Cox, M.D. Medical College of Indiana, Indianapolis, 1879; a member of the Wisconsin State Medical Society; formerly president of the Barron-Polk-Washburn-Sawyer and Burnett County Medical Society; a member of the American Association of Railway Surgeons; surgeon to the Chicago, St. Paul, Minneapolis and Omaha Railway, and Red Cross Hospital, Spooner, Wis.; a member of the local board of U. S. Pension Examining Surgeons; was killed in a railway wreck at Trinidad, Wash., September 30, aged 50.

Howard Sumner Dearing, M.D. Dartmouth Medical School, Hanover, N. H., 1882; of Boston; a member of the Massachusetts Medical Society; assistant professor of clinical medicine in Tufts College Medical School, Boston, Mass.; for more than twenty-five years an officer of the Massachusetts Volunteer Militia, retiring with the rank of lieutenant-colonel; major and surgeon of the First Massachusetts Heavy Artillery, U. S. V., during the Spanish-American War; died at his old home in East Waterboro, Maine, from cerebral hemorrhage, aged 52.

John Phillips Reynolds, M.D. Harvard Medical School, Boston, 1852; president of the American Gynecological Society in 1889; a member of the Massachusetts Medical Society; for twenty years professor of obstetrics in his alma mater; for several years a member of the Boston School Committee; physician to the Boston City Hospital, and consulting surgeon to the Boston Lying-In Hospital; died at his home in Boston, October 10, aged 83.

Robert Henry Jones, M.D. Medical College of Ohio, Cincinnati, 1878; formerly a member of the Clay County (Ill.) Medical Society; a member of the local board of U. S. pension examining surgeons; surgeon of the Illinois Soldiers and Sailors' Home, Quincy, in 1897 and 1898; died at his home in Lebanon, Ill., August 5, from paralysis and senile gangrene, aged 86.

Felix Jenkins, M.D. University of Maryland, Baltimore, 1849; of Baltimore; formerly a member of the Medical and

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

Public Health Cooperation in Minnesota

A most commendable movement was inaugurated at the recent meeting of the Minnesota State Medical Association held at Winona on October 12-14, when on the second day of the meeting the afternoon session was practically devoted to a symposium on the cooperation of state forces in Minnesota medicine, the object of the discussion being to evolve ideas and methods whereby all of the forces which make for better public health could be correlated and united. The titles in the symposium were as follows: "The State Medical Society," Dr. E. L. Tuohy, Duluth; "The State Board of Medical Examiners," Dr. F. A. Knights, Minneapolis; "The State Board of Health," Dr. H. M. Bracken, St. Paul, secretary of the State Board of Health; "The State Board of Control in its Medical Relationships," Dr. A. C. Rogers, Faribault; "The University of Minnesota in its Medical Relationships," Dr. Charles Lyman Greene, St. Paul; "The Medical Press," Dr. W. A. Jones, Minneapolis, editor of the *Journal of the Minnesota State Medical Association and the Northwestern Lancet;* "The Lay Press," Mr. Charles H. Grasty, of the *St. Paul Journal.*

The papers read were suggestive and the discussion which followed was enthusiastic and interesting. A committee was appointed to devise ways and means of cooperation of all the health forces of the state. Minnesota is in a peculiarly fortunate position for undertaking such coordinate work, as the only medical college in the state is the Medical Department of the State University, while the State Board of Health, the State Board of Medical Examiners, the Board of Control (having supervision over all state institutions) and the State Medical Association are all working with the utmost harmony and mutual understanding. Under these favorable conditions and with the best men in the state interested in the work, there is no reason why Minnesota cannot lead in a movement for better and more effective work in public health lines.

Census Plans

Hon. E. Dana Durand, director of the United States Census, has promulgated instructions for securing transcripts of deaths in selected registration states and cities. These transcripts are obtained every month by the Census Bureau from city and state registrars in the registration area and form the basis of the mortality statistics prepared by the Division of Vital Statistics under the supervision of Chief Statistician Cressy L. Wilbur. The enforcement of these new regulations will make possible the compilation of the most scientific and trustworthy mortality statistics ever compiled in connection with the United States census. The new revised version of the classification of the causes of death, adopted at the Paris conference for the second decennial revision of the international classification will go into effect Jan. 1, 1910. The new United States standard death certificate which the Vital Statistics Section of the American Public Health Association is expected to adopt at the coming meeting at Richmond, Va., will also be used for reporting of deaths of the registration area after January 1.

In his communication to state registrars, Mr. Durand emphasizes the importance of the exact agreement between the number of deaths as compiled by the state officials and by the Census Bureau. For the purpose of preventing discrepancies a monthly check list showing the deaths by months and weeks is supplied to each state registrar. The importance of accuracy and promptness in making reports is emphasized. City registrars are requested to observe these instructions the same as state registrars. Mr. Durand states that a city registrar should have in his hands the certificate for every death that occurs before any disposition is made of the body. Imperfect certificates or unsatisfactory statements of the cause of death should not be accepted. The cooperation of all registration officials is requested in order that the value of mortality statistics in the United States may be improved. Special attention is called to the importance of accurate and complete reports for 1910 in order that the complete returns for this year may be used as a basis of comparison.

Dr. Wilbur, chief statistician of the Division of Vital Statistics, states that the opportunity of inaugurating the use of the revised classification for mortality statistics in the actual census year is of the greatest value. In accordance with the resolution of the international commission, an official version of the revised titles used in the classification is being prepared in each language represented at the conference. The English translation has been made by Dr. Wilbur, assisted by the other American representatives, and Dr. G. W. Knibbs, commonwealth statistician of Australia. As a result, exactly the same tabular list will be used by all English-speaking countries. The next session of the conference for the revision of the International classification will be held in Paris in 1919, unless other arangements are made. It is the hope of those interested in the advancement of American vital statistics that the third decennial conference may be called by the American government and may meet at Washington.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Second Month—Fourth Weekly Meeting

DISEASES OF CEREBRAL VEINS AND SINUSES

PRIMARY, MARANTIC, THROMBOSIS: Etiology.—Age, prolonged illness, cachexiæ. Symptoms.—Preceding disease, venous stasis, local edema, mental symptoms.

SECONDARY, INFECTIVE, THROMBOSIS: Etiology.—Middle-ear disease, fractures, infections in nose, mouth and pharynx, erysipelas, anthrax. Symptoms.—Preceding infection, local symptoms, brain symptoms, septicemia.

CEREBRAL PALSIES OF CHILDREN

ETIOLOGY: (a) Prenatal conditions, lack of development, prematurity, porencephalia; (b) accidents at birth, protracted labors, vertex and breech presentations, abuse of forceps; (c) postnatal causes, age, infectious disease, injuries.

SYMPTOMS: Hemiplegic cases. Sudden onset, convulsions, loss of consciousness, development of hemiplegia, spasticity, exaggerated reflexes, contractures, attitude and gait. Atrophy of affected side. Athetosis. Tendency to epilepsy. Diplegic cases, may be paraplegic. Usually of prenatal or birth origin. Slow development of cranium, convulsive seizures, rigidity and contractions, upper and lower limbs involved. Lack of mental development, tendency to epilepsy and idiocy.

Monthly Meeting

Varieties of Aphasia and Significance of Each.
The Localization of the Lesion in Intracerebral Hemorrhage.
Early Diagnosis and Treatment of Cerebral Palsies of Children.

REFERENCE BOOKS FOR THE SECOND MONTH

Church and Peterson: Nervous and Mental Diseases.
Strümpell: Practice of Medicine.
Osler: Practice of Medicine.
Gowers: Brain and Crainal Nerves, vol. ii.
Mettler: Diseases of the Nervous System.
Sachs: Nervous Diseases of Children.

Nothing New Under the Sun.—It is curious to observe that the present scientific teaching on the basis of demonstrated fact is a return to a much earlier popular conception. Consumption was formerly popularly believed in some localities to be contagious. That belief rested on superficial observation, while the present teaching rests on demonstrated fact.—*Propaganda of the N. Y. State Charities Aid Association.*

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Arkansas: Regular, Little Rock, November 9. Sec., Dr. F. T. Murphy, Brinkley.
Connecticut: Homeopathic, New Haven, November 9. Sec., Dr. Edwin C. M. Hall, 82 Grand Ave.
Connecticut: Regular, City Hall, New Haven, November 9-10. Sec., Dr. Charles A. Tuttle, 196 York St.
Florida: Jacksonville, November 10-11. Sec., Dr. J. D. Fernandez.
Louisiana: Homeopathic, New Orleans, November 1. Sec., Dr. Gayle Aiken, 1102 St. Charles Ave.
Maine: Portland, November 9-10. Sec., Dr. Frank W. Searle, 806 Congress St.
Massachusetts: State House, Boston, November 9-11. Sec., Dr. E. B. Harvey, Room 159, State House.
Nebraska: Senate Chamber, State House, Lincoln, November 10-11. Sec., Dr. E. Arthur Carr, 141 South Twelfth St.
Nevada: Carson City, November 1. Sec., Dr. S. L. Lee.
Texas: Levy Bldg., Greenville, November 9-11. Sec., Dr. M. E. Daniel, Honey Grove.
West Virginia: Chancellor Hotel, Parkersburg, November 9-11 Sec., Dr. H. A. Barbee, Point Pleasant.

Kentucky July Report

Dr. J. N. McCormack, secretary of the Kentucky State Board of Health, reports the written examination held at Louisville, July 6-8, 1909. The number of subjects examined in was 10; percentage required to pass, 70. The total number of candidates examined was 124, of whom 107 passed and 17 failed. The following colleges were represented:

Chester Waterman, M.D., Central Islip, N. Y., to Miss Eleanor Alicia Atkinson of Yonkers, N. Y., October 6.

Thomas J. Nalley, M.D., St. Louis, to Mrs. Nellie Bradley of Seattle, Wash., at Minneapolis, Minn., October 1.

Frederick Tremaine Billings, M.D., Pittsburg, Pa., to Miss Romaine Le Moyne, at Garrison Forest, Md., October 6.

William Claiborne Powell, M.D., Petersburg, Va., to Miss Sara Breckenridge Early of Campbell county, Va., at Lynchburg, Va., October 5.

Deaths

Joseph P. Cox, M.D. Medical College of Indiana, Indianapolis, 1879; a member of the Wisconsin State Medical Society; formerly president of the Barron-Polk-Washburn-Sawyer and Burnett County Medical Society; a member of the American Association of Railway Surgeons; surgeon to the Chicago, St. Paul, Minneapolis and Omaha Railway, and Red Cross Hospital, Spooner, Wis.; a member of the local board of U. S. Pension Examining Surgeons; was killed in a railway wreck at Trinidad, Wash., September 30, aged 50.

Howard Sumner Dearing, M.D. Dartmouth Medical School, Hanover, N. H,, 1882; of Boston; a member of the Massachusetts Medical Society; assistant professor of clinical medicine in Tufts College Medical School, Boston, Mass.; for more than twenty-five years an officer of the Massachusetts Volunteer Militia, retiring with the rank of lieutenant-colonel; major and surgeon of the First Massachusetts Heavy Artillery, U. S. V., during the Spanish-American War; died at his old home in East Waterboro, Maine, from cerebral hemorrhage, aged 52.

John Phillips Reynolds, M.D. Harvard Medical School, Boston, 1852; president of the American Gynecological Society in 1889; a member of the Massachusetts Medical Society; for twenty years professor of obstetrics in his alma mater; for several years a member of the Boston School Committee; physician to the Boston City Hospital, and consulting surgeon to the Boston Lying-In Hospital; died at his home in Boston, October 10, aged 83.

Robert Henry Jones, M.D. Medical College of Ohio, Cincinnati, 1878; formerly a member of the Clay County (Ill.) Medical Society; a member of the local board of U. S. pension examining surgeons; surgeon of the Illinois Soldiers and Sailors' Home, Quincy, in 1897 and 1898; died at his home in Lebanon, Ill., August 5. from paralysis and senile gangrene, aged 86.

Felix Jenkins, M.D. University of Maryland, Baltimore, 1849; of Baltimore; formerly a member of the Medical and

Chirurgical Faculty of Maryland; from 1850 to 1854 resident physician at the University Hospital, Baltimore; died at the home of his daughter in Towson, Md., October 9, from senile debility, following a fracture of the hip, aged 83.

Samuel Carter Van Antwerp, M.D. University of Michigan, Ann Arbor, 1872; a member of the American Medical Association; and once president of the Kalamazoo County (Mich.) Medical Society; secretary of the school board of Vicksburg, Mich., for many years; a veteran of the Civil War; died at his home in Vicksburg, October 4, aged 62.

Henry C. Palmer, M.D. New York University, New York City, 1865; of Utica; a member of the Medical Society of the State of New York; assistant surgeon of a New York regiment during the Civil War; physician to the Faxton Hospital, Utica; died in the Hamot Hospital, Erie, Pa., October 6, from pneumonia, aged 68.

James McClure, M.D. Starling Medical College, Columbus, Ohio, 1864; of Marietta, Ohio; a member of the American Medical Association; assistant surgeon of the Twenty-third Ohio Volunteer Infantry during the Civil War; died in a hospital in Chicago, October 6, aged 74.

Amos Northrop Bellinger, M.D. Medical College of the State of South Carolina, Charleston, 1860; for many years physician to the Charleston county jail; a surgeon in the Confederate service throughout the Civil War; died at his home in Charleston, October 3, aged 72.

Nelson Tillman Chenoweth, M.D. Eclectic Medical Institute, Cincinnati, 1867; Miami Medical College, Cincinnati, 1883; a member of the Indiana State Medical Association; a veteran of the Civil War; died at his home in Windsor, Ind., October 8, from asthma, aged 72.

Charles Arthur Elliott, M.D. Western University, London, Ont., 1894; of Harrison Hot Springs, B. C.; died in Vancouver, B. C., September 30, from the effects of a fracture of the spine, due to a runaway accident a month before, aged 40.

Edward O. Peyton, M.D. Jefferson Medical College, Philadelphia, 1859; a surgeon in the Confederate service during the Civil War; died at his home in Greenville, Va., February 4, from uremia, due to prostatic hypertrophy, aged 75.

Paul Randall Abell, M.D. Long Island College Hospital, Brooklyn, N. Y., 1902; of Norwich, N. Y.; a member and formerly president of the Susquehanna Valley Medical Society; died in Norwich, August 24, from paresis, aged 31.

Augustus F. Tulley, M.D. Cincinnati College of Medicine and Surgery, 1879; of Brazil, Ind.; formerly secretary of the board of health of Clay county; died at the home of his daughter in Mooresville, Ind., October 8, from paresis, aged 63.

Isham S. Burdett, M.D. Missouri Medical College, St. Louis, 1861; a member of the Lincoln County (Ky.) Medical Society; an eye and ear specialist of Crab Orchard; died at his home in that place, April 30, from nephritis, aged 75.

John M. Bearden, M.D. Southern Medical College, Atlanta, Ga., 1881; of Ellijay, Ga.; died in his barn, October 7, from the effects of a gunshot wound of the head, believed to have been self-inflicted with suicidal intent.

Eugene A. Gaston, M.D. University of Pennsylvania, Philadelphia, 1867; a member of the Kansas Medical Society and physician of Pratt county; died at his home in Pratt, July 21, from spinal sclerosis, aged 64.

Robert Morrison, M.D. Jefferson Medical College, Philadelphia, 1883; a member of the American Medical Association; died suddenly at his home in Sheridanville, Pa., October 3, from heart disease, aged 54.

G. William Park, M.D. Medico-Chirurgical College of Philadelphia, 1897; formerly of Harrisburg, Pa.; died in the Glockner Sanatorium, Colorado Springs, Colo., October, 2, from tuberculosis, aged 35.

Abraham F. Crans, M.D. University of Buffalo (N. Y.) 1890; formerly of Owego, N. Y., and health officer and trustee of that city; died at his home in Olyphant, Pa., October 2, from heart disease, aged 68.

Charles E. Coppedge, M.D. Kansas Medical College, Topeka, 1906; a member of the American Medical Association; died at his home in Bixby, Okla., August 5, from typhoid fever, aged 39.

Wilbert Henry Monroe, M.D. Rush Medical College, 1884; a member of the American Medical Association; died at his home in Merrill, Wis., October 4, from tuberculosis, aged 53.

Daniel Garrison, M.D. Jefferson Medical College, Philadelphia, 1880; a member of the American Medical Association; died at his home in West Collingswood, N. J., October 4, aged 62.

Reynolds C. Taylor (license, Ill., years of practice, 1877); a homeopathic practitioner of Carmi, Ill.; a veteran of the Civil War; died at his home, October 11.

George C. Potter, M.D. Northwestern Medical College, St. Joseph, Mo., 1882; died at his home in St. Joseph, October 7, from cerebral hemorrhage, aged 57.

William A. Hassler, M.D. Jefferson Medical College, Philadelphia, 1866; died at his home in Allentown, Pa., October 6, from cerebral hemorrhage, aged 68.

John S. Mushat, M.D. University of Virginia, Charlottesville, 1895; of Fountain, Colo.; died at his former home in Birmingham, Ala., September 30, aged 34.

William H. Burroughs, M.D. Medical College of Indiana, Indianapolis, 1886; died at his home in Shannondale, Ind., October 8, from nephritis, aged 59.

Irvin Calhoun Wright, M.D. Washington University, St. Louis, 1873; died at his home in Logan, Ohio, October 7, from cerebral hemorrhage, aged 64.

Orson Valentine Thayer, M.D. Vermont Medical College, Woodstock, 1846; died at his home in Hillcrest, San Diego, Cal., September 28, aged 86.

John W. Huddleston, M.D. Medical College of Virginia, Richmond, 1906; died at his home in Bedford City, Va., October 7, from tuberculosis, aged 33.

J. Thomas Calvert, M.D. University of Tennessee, Nashville, 1882; died at his home in Spartanburg, S. C., October 6, aged 53.

Clarence E. Tinsley, M.D. Louisville (Ky.) Medical College, 1906; died at his home in New Waverly, Texas, September 22, aged 31.

Cyrus Pickett, M.D. Eclectic Medical Institute, Cincinnati, 1870; died at his home in Dunning, Neb., August 7, aged 69.

Joseph Antoine Rodier, M.D. Laval University, Quebec, 1889; died at his home in Montreal, October 4, aged 46.

Thirty-Fifth Annual Meeting, held at St. Louis, Oct. 12-14, 1909

The President, Dr. John A. Witherspoon, Nashville, Tenn., in the Chair

Addresses of welcome were delivered by Dr. Tinsley Brown, president of the Missouri State Medical Society, and by Dr. Clarence M. Nicholson, president of the St. Louis Medical Society. The response on behalf of the association to these addresses was made by Dr. T. Hunt Stucky, Louisville, Ky.

Officers Elected

The following officers were elected for the ensuing year: President, Dr. Frank Parsons Norbury, Kankakee, Ill.: vice-presidents, Drs. George W. Cale, Jr., St. Louis, and William V. Laws, Hot Springs, Ark.; secretary, Dr. Henry Enos Tuley, Louisville, Ky. (re-elected); treasurer, Dr. Samuel Cecil Stanton, Chicago (re-elected). The invitation of the Wayne County (Mich.) Medical Society to hold the 1910 meeting at Detroit was accepted.

Treatment of Peritoneal Infections in the Light of the Protective Nature of Peritonitis

Dr. Channing W. Barrett, Chicago: The spreading and absorption of infection is a process dangerous to life and inflammation is a reaction beneficial to the patient in the presence of infection. I draw the following conclusions in regard to the treatment of peritoneal infections: 1. Peritoneal infection can be prevented by the greatest care in operative work and by the approved use of such means as are best calculated to prevent peritoneal infection from other sources. An infected appendix is one which, by reason of kinking, the presence of a foreign body, etc., is likely to become infected and should be removed. Pathologic conditions of the intestines, gall-bladder, uterus, tubes and ovaries should receive attention. 2. In the presence of existing peritoneal infection an effort should be made to discover its origin and further infection prevented, if possible. 3. Easily and safely removable sources of infection, such as a badly infected appendix or in some instances an infected kidney, ovary or uterus, should be removed. But when this is done during an acute process it should be done not because the structure is inflamed, but because the source of infection is being thereby entirely or largely removed. 4. All physical activity of the patient, massage, peristalsis, etc., which will tend to distribute infection should be avoided. 5. The development of bacteria in, and their distribution through, the intestinal tract should be lessened by the removal of gaseous fluid contents of stomach, lavage, rectal flushings and, if necessary, as is sometimes the case, by enterostomy during the operation. 6. Whenever and wherever the area of infection can be reached or whenever the infectious material exists in the general peritoneal cavity that can be drained, drainage should be established. The tendency of infection is to break down its limiting wall and to increase its area and the damage done not only depends on the virulence of the infection, but on the area involved. The application of this principle to the treatment of appendiceal infection is: (1) The removal of troublesome appendices before the acute onset of infection; (2) the removal of the infected appendix before any considerable peritoneal infection takes place; (3) drainage of localized appendiceal abscess with removal of the appendix if it is easily found; (4) drainage of the peritoneal infection with the removal of the diseased appendix if easily found, if a localized wall has not formed, the absence of wall or weakness of wall making drainage very urgent; (5) treatment of inflammatory wall is a benign and protective process in conditions interfering with the bowels in a mechanical way when it may have to be disturbed by the existence of the distributing infection; (6) rest, general and local, emptying the intestinal tract, dilution of the toxins and supportive treatment with salt solution should be made use of as in keeping with or without operative treatment.

(*To be continued*)

VIRGINIA STATE MEDICAL SOCIETY

Fortieth Annual Meeting, held at Roanoke, Oct. 5-8, 1909

Case of Chronic Invagination of Sigmoid and Rectum

Dr. E. H. Terrell, Richmond: A medical student, eighteen months ago suffered from obstinate constipation which grew worse; stool was secured with difficulty, and it was liquid and mucus, with sense of insufficient evacuation. Medicines of various kinds were given by mouth and injection. Finally he was referred to Dr. Hazen, an electrotherapeutist. Electric treatment was given for several weeks at regular intervals with marked improvement, and now satisfactory results.

Ova of House-Fly Passed from Child's Rectum

Dr. W. B. Barham, Newsoms: The peculiar worms passed from rectum of a little girl, caused irritation which at first was thought to be piles, but examination showed no hemorrhoids. Hookworms were then thought of. A specimen was sent to Washington, and the report stated that the worm was the ova of the house-fly. I should like to know if others have had any similar experience.

DISCUSSION

Dr. W. A. Plecker, Hampton: I had a similar case in a colored girl, only the worms were in the vagina instead of the rectum. I used a phenol wash and cleaned them out readily.

Case of Rupture of Posterior Wall of Uterus

Dr. R. D. Garcin, Richmond: So far as I am able to find out, this is the only case of the kind in Richmond in the last forty years in which the patient recovered. The patient was a primipara aged 27; posterior occipital presentation, third position. I applied forceps, after consultation, and finally delivered the woman but ruptured the posterior uterine wall. Operation was followed by tedious convalescence and recovery.

DISCUSSION

Dr. W. E. McGuire, Richmond: About a year ago I was called to see a patient at 4 a. m. I took her to the hospital at 8 o'clock. The patient was lying very comfortably in bed and had no pain; I did not examine her. The obstetrician arrived at 11 o'clock. I opened the abdomen and found a large dead baby in the abdomen up under the liver, the placenta in the abdominal cavity, and the uterus torn three-fourths of the whole circumference. Only about a quart of blood had escaped; the uterus was well contracted. I did hysterectomy, the patient recovered and in eighteen days left the hospital.

Dr. Garcin: My case occurred in 1907.

Acid Intoxication

Dr. Douglas Vanderhoof, Richmond: I have reported two cases of acid intoxication to the Richmond Academy, and in the past summer found the fourth case. This condition is characterized by two signs, peculiar breathing, very rapid and very deep, different from that in pneumonia, which is very rapid but shallow; and by fruity, sweet-smelling odor to breath, which fills the room. The urine is loaded with acetone. The treatment is not generally understood. I saw one case in which the diet had been cut down to almost water alone. These patients need sugar, their condition is that of the diabetic who is dying. Their high temperature burns up carbohydrates. I give ordinary cane sugar by mouth, every two hours. If the patient cannot swallow I give the sugar under the skin.

Dilatation of Uterus

Dr. M. W. Peyser, Richmond,: This paper deals with the substitution of painless for painful dilatation of the uterus. Usually this procedure is very painful. Recently I have been doing dilatation with the negative pole of a battery. In one case at first the os would hardly admit the smallest sound; at the end of the fourth treatment it admitted No. 35 French.

SYMPOSIUM ON PNEUMONIA

Lobar Pneumonia in Children

Dr. W. E. Anderson, Farmville: Lobar pneumonia in children does not differ much from the disease in adults. If Holt were in Virginia, and away from the crowded districts of New York, he would not have written some things he has in his book. Children in congested districts are always badly nourished, and that is a cause of the high mortality. Lobular pneumonia is more usually a complication of pertussis, measles, etc. Disturbance of pulse and absence of vesicular murmur are points in diagnosis. It is hard to give medicines, or even enough water, on account of dyspnea. Relief comes more quickly to children than to adults. More fatal cases follow measles than any other disease. Generally these children have too little fresh air and too much cover. More air early means less need of the oxygen tank later. Oil silk interferes with the action of the skin, is uncomfortable, and there is danger of taking cold when it is removed. In breast-fed infants water should be given before nursing, as it helps elimination and dilutes the milk. Tincture of strophanthus, one drop and up, may be given according to age; rarely digitalis is necessary. A mustard bath is good. I am convinced that we give too much medicine.

Treatment of Pneumonia

Dr. W. A. Plecker, Hampton: The patient should have the purest air possible. A low temperature is stimulating, but the patient must be kept warmly covered. Fresh-air treatment now meets with less opposition than formerly. The bowels, skin and kidneys must be stimulated for elimination; water should be given freely. Salt solution may be given subcutaneously if there is falling blood pressure. Creosote enhances the antiseptic value of blood. If the pulse be kept below 100 the patient's chances for recovery are better. There is a revulsion of feeling in regard to alcohol; there are better agents, except in case of old topers. The mortality is 15 per cent. lower when it is not used. Sleep is of more value to children than either food or medicines.

DISCUSSION

Dr. Hawes Campbell, Enfield: Mortality from pneumonia in country practice is not nearly so great as stated in the average text-book. I see from 30 to 40 cases in Tidewater every winter, and I can truthfully say that the mortality is not over 10 per cent. The amount of toxemia is not dependent on the size of the area involved. I am not prepared to join in the crusade against coal-tar derivatives. I recall one case in which the temperature remained 106 F. some hours. A sponge bath made the patient purple; I gave phenacetin guarded by caffein, and believe that the child owes its life to this prescription. I abandoned digitalis, as it produces a jerky pulse; strophanthus is better.

Dr. Thomas, Washington, D. C.: It has beeen noticed of recent years that abdominal symptoms are present in pneumonia. Abdominal operations have been done when the patient had pneumonia. This mistake is a serious one, as pneumonia usually contraindicates operations. Many of these operations are never reported. An early symptom in children is exaggerated breathing in the opposite lung.

Dr. R. K. Flannagan, Charlottesville: As a health officer, I want to say: Quarantine against measles as much as against smallpox. The sooner we do this, the sooner we will reduce the mortality of pneumonia.

Dr. T. M. Cherry, Norton: I have not heard anything of the mud-poltice, and I am glad of it. I seldom use alcohol and am still looking for a specific.

Clinical Significance of Aërophagia

Dr. Douglas Vanderhoof, Richmond: The term aërophagia is often erroneously used for fermentative dyspepsia. It is a condition similar to "wind sucking" in horses, and is a neurosis.

DISCUSSION

Dr. M. W. Peyser, Richmond: In some cases the condition is due not to swallowed air but to gas passing from the blood vessels. If the patient's attention is distracted the belching then stops.

Dr. A. G. Brown, Jr., Richmond: This is one of the symptoms of angina pectoris not in the text-books.

Paratyphoid

Drs. J. S. Sellers and H. T. Hoskins, Weyers Cave: The literature on this subject is scarce. The Germans claim that the disease is due to a germ in meat. I treated three patients in one family—the first on March 26, the second four days later and the third nine days later. Water was obtained from an old cistern. Uncooked vegetables may be responsible for paratyphoid in many instances.

What the Practising Physician Can Do in Prevention of Typhoid Fever

Dr. L. L. Lumsden, Washington, D. C.: Preventive measures are known, but it is a problem to carry them out. Typhoid is fourth in the mortality list, in the United States. Careless disposal of excreta is nearly always the cause. The conduct of the physician at the house and in the sick-room, washing hands when leaving, etc., is an example to the family. He should advise only those measures that can be readily carried out—boiling the water, scrubbing hands, and isolation. Country physicians should have properly constructed earth closets as an object lesson. They should also cooperate with the health officers.

DISCUSSION

Dr. A. W. Freeman, Richmond: Typhoid is largely a rural disease. In August nearly 4,000 cases were reported in Virginia, of which three-fourths were in the country or small towns. The place to prevent its spread is at the bedside of the patient. Three points only are to be borne in mind in dealing with excreta, viz.: keep off of ground, keep dry, and keep flies away, till disposed of.

Economic Value of Early Diagnosis of Pulmonary Tuberculosis

Dr. Truman A. Parker, Richmond: The average practitioner can diagnose tuberculosis if careful. Physical signs are not necessary. Two or three negative sputum examinations do not exclude tuberculosis. Family history is not necessary. A few symptoms, such as slight loss of weight, little cough, paleness of mucous membranes, are suggestive. Subnormal morning temperature, followed by a rise to 99 or 100 F., is strongly suggestive. Fit of clothing may give hint of loss in weight.

DISCUSSION

Dr. Tuxberry, Catawba Sanatorium: I do not think Dr. Parker laid stress enough on combining the clinical picture with the physical diagnosis.

Dr. A. L. Gray, Richmond: Physical diagnosis is only to be added to the *x*-ray. I maintain that with the *x*-ray diagnosis can be made earlier than by any other means. Tuberculin reacts sometimes when tubercle bacilli are not present. Depth of shadow is an index of activity of disease.

Dr. W. A. Plecker, Hampton: There are very few greater responsibilities than that of diagnosing a case of tuberculosis. General practitioners do not see enough cases to become skilful.

Dr. Thomas, Washington, D. C.: I agree with Dr. Tuxberry that physicians should be encouraged to make physical examinations. It makes great difference to a patient to say that he may have tuberculosis. We should take this into consideration even in provisional diagnosis.

Dr. Parker: Carry in mind the little points mentioned in the text-books. If quinin does not relieve the temperature, watch the patient closely.

Treatment of Fractures Involving the Elbow

Dr. A. R. Shands, Washington, D. C.: I urge operative treatment of these fractures in children when the *x*-ray shows improper position of the fragments. After operation I put up the elbow acutely flexed (Jones' position). I insert drill through the fragments and let it project through the dressings; I leave this for two weeks. It is an ideal method. The plaster dressing is removed in three weeks. Perfect functional result was obtained in over 20 cases. Ischemic paralysis may occur if the splints are too tight. It is important to take *x*-ray picture in more than one plane.

Sterilization of Criminals

Dr. C. V. Carrington, Richmond: This procedure is new and hedged about by ideas of cruel and unusual punishment, but it is far-reaching in its deterrent effects. Four states —Indiana, Utah, Connecticut and California—have laws permitting this operation. The first-named state has sterilized several hundred men. Reproduction of criminals should be prevented. I do not say which criminals should or should not be sterilized. Simple operation, resection of the vas deferens, generally under cocain, is done through a small incision which is then closed by one or two stitches. I have sterilized four men in the penitentiary. Good results were obtained in the first two; the third and fourth are too recent to report final results.

DISCUSSION

Dr. E. T. Brady, Abingdon: Sterilization of epileptics is as important as criminals and is closely correlated. One county in this state is noted for epileptics, and this county has the record for crime. It is hard to get legislators to agree.

Dr. L. G. Pedigo, Roanoke: If we read Lombroso and Nordau on heredity we find epilepsy interchangeable with criminal types. Sterilizing criminals only shuts off a small source of supply. The whole group of neuroses breeds degenerates and criminals in one generation, and perhaps genius in the next.

Dr. C. V. Carrington: I do not advocate this operation as a punishment, but as a health measure, though I do think it well to stop the breed. I have operated only on insane patients. The testicles do not atrophy.

Syphilis and the Negro

Dr. Thomas W. Murrell, Richmond: There is a lack of statistics and consequent ignorance on this subject. Southern men are most conversant with things standing in the way of the advancement of the negro. There are no statistics by the census bureau on this subject south of the Potomac and Ohio rivers, where 28 per cent. of the negroes live. During slavery days he was made to preserve his body; his master's own physician attended him when sick; good hygiene and care caused him to outstrip the whites in fecundity. After that period he was free, not only to live, but to die as well, and to be infected with every disease. Disease and dissipation have done their work well. Then there were only a few insane negroes, confined in almshouses and jails; now 1,500 are confined in the Virginia state asylum, an increase of over 1,000 per cent. Tuberculosis is often spoken of as a scourge, but there must be twenty syphilitic negroes to every tuberculous one. There is greater prominence of pustular syphilides, indicating less resistance. Serotherapy is the only hope, but till it is perfected mercury and potassium iodid must be given by mouth. Pain is too dreaded by the negro to permit hypodermic medication and he will not take the trouble to use inunction. Every syphilitic should be registered and forced to take treatment.

DISCUSSION

Dr. P. B. Barringer, Blacksburg: I am glad to see the younger men taking up this subject. Syphilis produces abortion and so prevents reproduction. The negro carries diseases to give them to the white man, as uncinariasis.

Dr. H. E. Jones, Roanoke: The only defect in Dr. Murrell's paper is that he fails to give us a remedy. I think one great preventive is circumcision; the Jews are less susceptible to the infectious and contagious diseases for this reason. The people of a certain South Sea island were free from all infectious diseases till they were infected with syphilis by English sailors; tuberculosis then broke out and practically depopulated the island. Immunity was destroyed by incurring syphilis. Circumcision will tend to help acquire immunity.

Dr. L. G. Pedigo, Roanoke: One factor in cutting down fecundity is miscegenation. Another factor in thinning the ranks is the congestion in railroad towns; also the tremendous development of the cocain habit. Immigration from Europe increases the white but not the colored population. This giving away of the inferior to the superior race is seen in New Zealand in the gradual extinction of the Maoris. The only hope of the southern part of the United States is just these forces, leading to the gradual extermination of the negro.

Dr. Brady, Abingdon: The time has arrived when we should inject these sociologic questions into our meetings. Syphilis is a terrible menace, and it is providential that tertiary syphilis is not communicable; otherwise our children would be in great danger of infection from nurse-maids.

Dr. C. M. Miller, Richmond: I have found in dispensary practice that a little potassium iodid is good for a negro with any disease. Gumma of the throat is frequent. Their response to antisyphiltic remedies is marvelous.

Dr. T. W. Murrell: In this matter we have a problem such as exists probably in no other part of the world. A large percentage of students in our medical school are from the North, and they say they had no idea of the prevalence of syphilis in the negro.

Duty of the Physician to His Municipality

Dr. Roy K. Flannagan, Charlottesville: The public is not alive to the good of health departments. The health department is absolutely dependent on the physician for reports of preventable diseases. With increasing knowledge, people are falling into line. The council needs the physician; the school board needs his qualities of heart and head and hand. He owes expression of his thought to the public either by spoken or written word. Each physician bears his torch; it should be a flaming arc light. On the medical profession depends largely the checking of the social evil, if it is ever to be checked. I deplore the sentiment that seals the physician's lips to the secret in reference to the victim of marital infidelity. It is his duty to get closer in touch with his professional brethren in the local society. There should be a publicity committee to enlighten the laity on the problems confronting society as it affects them. Every agency is ours to use, not bound by sectarian tenets.

Pellagra

Dr. Vanderhoof, Richmond: I wish to place on record a case of pellagra brought to Richmond by Dr. J. W. Smith, of Cumberland. The patient is a white woman, aged 45, a farmer's wife. Past history is negative. Since last April she has had a peculiar vertigo, with headache; she feels continually as if she were drunk. The backs of the hands peeled off; there was parchment-like erythema, like sunburn, half way up the arm. She had chronic diarrhea for the past six months, from four to six bowel movements a day. There was characteristic melancholia, which to a stranger was not marked, but her physician said that there was distinct mental change. There was no stomatitis, but a gumboil. There was no ataxia; the reflexes were active but not exaggerated. Blood examination showed anemia. Urine was negative, except excess of indican; stools negative except excessive mucus. She has grown progressively worse; the hands exfoliated a second time. She developed stomatitis, continued to lose weight and the mental symptoms became more serious. The interesting thing is that she has not used corn diet, does not eat corn products half a dozen times a year and does not use corn whisky.

Clinical Aspects of Hyperthyroidism

Dr. McCaw Tompkins, Richmond: Slight cases are often overlooked and diagnosed as neurasthenia, hysteria, etc. Cases are of two kinds, nervous and toxic. Most cases never progress beyond a certain point. There is a widespread belief that surgery offers promise of relief, but the mortality is high and myxedema may be thus substituted.

Present Status of Treatment of Goiter

Dr. LeGrand Guerry, Columbia, S. C.: This is one of the splendid achievements of modern surgery when we consider the mortality and certainty of cure. Ten years ago the mortality was from 10 to 20 per cent. Surgeons were only willing to operate when forced to, a fact which explains the percentage. There are two classes of goiter—simple and exophthalmic. Medicine cannot influence the encapsulated gland. In simple goiters occurring at puberty, recovery generally ensues. If the thyroid grows after the age of 35 it is wise to suspect malignancy. There is hardly a class of cases which can be approached with better chance of cure. The patient should be made to understand that the good gland is left *in situ* and only the tumor removed. Nature gives one-sixth as much blood to the thyroid as to the brain. Serotherapy is not uniform in results. Drugs should be given only reasonable trial; if no result, surgery should be tried.

DISCUSSION

Dr. Royster, Raleigh, N. C.: The most encouraging improvement in surgery in the last five years is that of the thyroid and the prostate. In thyroid surgery this is due to the greater knowledge of pathology. Study after removal gives the keynote for treatment. If little blood is lost mortality is almost *nil*.

Dr. A. L. Gray, Richmond: With the *x*-ray in the hands of a competent man definite good may be expected in 75 per cent. of cases, with a fair number of cures. Early cases are more amenable. The *x*-ray is of value both before and after operation.

INDIANA STATE MEDICAL ASSOCIATION

Sixtieth Annual Session, held at Terre Haute, Oct. 7-8, 1909

(Continued from page 1320)

Heredity and Disease

Dr. Joseph Collins, New York: It is now a part of the intellectual creed of the educated that man is a product of evolution, due largely to natural and sexual selection and adaptation. Modern civilization and humanitarianism have cramped the action of these and from the point of evolution man has ceased to progress. If there is to be a renaissance the primary factors of evolution, variation and heredity, must be discovered. The physician has unique opportunity for doing this. He learns that heredity is the most important factor in his effort to interpret and thwart disease. His attitude toward disease has changed. It is to prevent. To obviate predisposition is frequently paramount to preventing disease. The physical basis of inheritance is the fertilized ovum. Initial heredity is dual, as stated by Galton, who formulated the law of ancestral inheritance, and by Karl Pearson, who shows its application, and as shown by the law of Mendel, which defines the dominant and recessive units concerned in the constitution of organisms. Complete family records properly interpreted will reveal the secrets of heredity in disease. Acquired characteristics are not transmitted. We can do little to influence succeeding generations through nurture, but a great deal by aiding Nature. Hereditable diseases of the blood, muscular and nervous system are most striking, but especially striking are the abiotrophies of Gowers. A predisposition to disease is inherited and there is evidence to show that at least partial immunity may be inherited. The departures from normal termed degeneracy are inherited and the functional diseases of degeneracy are remarkable for their interchangeability, and the same neuropath may have at different periods of life epilepsy, tic, hysteria, psychasthenia and migraine. Insanity is definitely related to pathologic heredity and nervous exhaustion may be an expression of inadequate neural endowment. Predisposition encompasses the hereditability of infections and parasitic diseases. The study of prevention has directed the keenest efforts of the profession toward the microbic causes of disease to the neglect of the most important factor, heredity. Present-day humanitarianism seeks to benefit the individual, but if the object is the improvement of the human race the biologist and the student of heredity should be taken more intimately into counsel. Galton tells us "the first object of eugenics is to check the birth-rate of the unfit," and if the land shall not be desolate because of them that dwell therein for the fruit of their doing, we must increase the birth-rate of the fit. The physician should enlarge the sphere of his usefulness by studying biology, for, as Descartes said, if man is to be perfected the means of perfecting him must be sought in the medical sciences. Let us to our task.

President's Address: The Art of Medicine

Dr. George D. Kahlo, French Lick: Scientific research has given us an insight into disease scarcely dreamed of a generation or two ago. Modern sanitation has eliminated many of the greatest human scourges and diagnosis is approching an exact science. Yet in spite of this progress there is a widespread tendency in the public to self-treatment and the acceptance of occult doctrines which can but result in needless suffering and the actual sacrifice of human life. The education of the public in medical and sanitary matters in order to procure needed legislation has contributed to this tendency to self-treatment, as has also the tendency of the profession to become laboratory experimenters rather than clinicians. The patient wants relief. Also there is the belief that medical treatment always means drugs. Great epidemics of contagion have been eliminated, but modern life and luxury have developed neuroses and psychoses in the cure of which psychic influences play an important rôle, and ridicule cannot overcome these cults. Medicine is still an art. To attempt to treat a purely psychic condition by physical means is just as illogical as to rely on mental healing for the relief of physical ailments. In the borderland cases the art of the physician comes into play, and the criticism that we are sacrificing our art on the altar of science is not altogether unjust. Medicine is no longer shrouded in mystery, and treatment that is so narrowed by orthodoxy and so hampered by scientific prejudice that it is lacking in that most valuable of all good qualities, common sense, is inevitably calculated to discredit the medical art.

Cesarean Section as a Means of Rapid Delivery in Eclampsia

Dr. Walker Schell, Terre Haute: Cesarean section has its place and offers a valuable resource when rapid delivery must be accomplished in eclampsia. Its mortality has sunk to 10 per cent. in all cases, and to 2.5 per cent. in patients uninfected by previous attempts at delivery. Eclampsia occurs in about 1 per cent. of all pregnant women, the mortality in the mothers is 25 per cent. and in the children 50 per cent. Section, therefore, with its low mortality, offers the safest and quickest means of delivery, less traumatism being inflicted than by attempts at dilatation or rapid forceps extractions. The mother operated on at seven months and the living child presented here are evidence of its value.

DISCUSSION

Dr. Miles F. Porter, Fort Wayne: The case of the mother and child presented by Dr. Schell is a strong, clear and forcible illustration of a man being guided by surgical judgment and wisdom rather than by the worship of tradition, and we should not lose sight of the fact that by a clean surgical operation he has avoided the subsequent morbidity entailed almost unavoidably by the so-called obstetric procedures.

Results of Neglected Appendicitis

Dr. B. VanSweringen, Fort Wayne: Early operation is indicated in practically all cases, and from this point of view the appellation, "neglected," is correct, not always on the part of the physician, but many times by the patient or his family. The Germans are too conservative in treatment, waiting for suppurative processes to become walled off. In the meaning of this paper, these patients are neglected because the time was when this disease could have been cured by operation, without abscess forming and without complications and sequelæ such as phlebitis and pylephlebitis of various veins, abscess of the liver, pelvic inflammation, necrosis of the intestinal walls, fistulas, pneumonia, pleurisy, ileus, adhesions, etc. The dictum of Moynihan that in many cases of abscess the removal of the appendix is unnecessary is not always wise practice. In fatal cases, adhesions do not form and when present they are evidence that the body's defensive powers are capable of dealing with the infection already present and therefore the diseased structures should be ablated whenever possible.

DISCUSSION

Dr. George J. Cook, Indianapolis: In recent years the neglect is not so often with the general practitioner, because he is able now to recognize these cases quickly and if he does not operate himself he refers them to a surgeon. The people also are becoming better educated to the importance of operation and do not so often object to prompt action. In the case of a little girl who had eaten some raw turnips a bellyache following in a few hours was diagnosed by two general practitioners appendicitis, and operation within twenty-four hours from the onset revealed a gangrenous appendix. That could not be said to have been a neglected case. The surroundings also determine sometimes whether one can do an immediate operation or whether one must trust to an ice bag and strychnin and starvation. Suppose a physician has a case of general peritonitis on the third day, with pulse of 130 or 140 and a high temperature? If he operates the shock of the anesthetic and a complete operation will kill the patient. My rule in such cases is to adopt the Ochsner treatment plus an opening in the abdomen done under local anesthesia to let the pus and serum out.

Dr. David Ross, Indianapolis: I have sometimes doubted whether it is these acute cases in which the patient most unquestionably can be and, every one agrees, should be operated on, that are the most neglected. I think we meet these cases most frequently in children in whom there are so many things which might cause abdominal pain. The physician is likely to make a snap diagnosis of colic and let it go at that. These children recover, but have attacks again and again until finally some one makes the diagnosis when the time for operation has passed. These are the most frequently neglected cases. In many instances the worst features of cases that prove to be chronic appendicitis are not the localized conditions about the appendix, but certain forms of nervousness or general ill health, and when the diagnosis is finally made and operation done the nervousness and ill health disappear. Morris of New York calls attention to the fibrous appendix that may cause general symptoms of ill health and make life a burden without being a menace to it; the symptoms clear up when the patient is operated on. These might be termed cases of neglected appendicitis.

Dr. A. M. Hayden, Evansville: There are many cases of catarrhal appendicitis producing distress in the stomach. The condition is often called dyspepsia, and the appendix is not suspected by the patient. I believe eight-tenths of all cases of chronic indigestion are due to some disturbance about the appendix, involving the ascending and transverse colon. Sometimes the symptoms are negative. The patient may complain of pain, but with no increased pulse or temperature, and operation reveals a gangrenous appendix. I recall such a case in a girl 16 years old, in whom within twenty-four hours from the commencement of the attack, gangrenous appendix and cecum were found. This class of cases is overlooked by the surgeon, as well as by the general practitioner.

Dr. Joseph R. Eastman, Indianapolis: When we compare the teaching of men like Deaver, who says operate in every case on the spot, and Ochsner who says put on an ice bag, give strychnin and wait, one's first impression is that both are incorrigible liars, for one operates at once in about as large a number of cases as the other; I confess I am frequently in a quandary as to what to do. I recently had a patient who worked in the harvest field until 4 o'clock one day, and I operated on him the next day immediately after noon, and following the knife wound the pus flowed profusely. It seems inconceivable that so much pus could develop in such a short time, but it has been suggested that possibly the peritoneum can secrete fluid with the same rapidity that it can absorb fluid.

Dr. Schmauss, Alexandria: If the heart be examined in cases of appendicitis pursuing a rather virulent course, not infrequently an endocarditis will be found, which is a serious condition, and unless attended to may lead to permanent crippling of the organ. I do not agree with Dr. Cook that physicians as a general rule recognize appendicitis; I have been surprised to find typical cases being treated as typhoid, and I know of two patients who died recently in whom the disease was not recognized as appendicitis.

Dr. H. O. Pantzer, Indianapolis: A class of cases of neglected appendicitis not referred to here should be mentioned, in which pus is early secreted and the patient makes an apparent recovery by the discharge of the pus through the bowel. These patients recover slowly and weeks of absorption of pus give rise to hyaline degeneration of all the glandular organs, particularly in young individuals. I remember one case in which the family congratulated itself that they had escaped the surgeon. The child recovered seemingly, and in two and a half months was sent back to school. But in less than two years she died with parenchymatous nephritis.

Iliohypogastric Hyperesthesia

Dr. M. A. Austin, Anderson: We have too long denied the possible relation between functional disorders and a mental state. In no class of cases does the surgeon find so many contradictory results and wasted effort as in pelvic complaints of women. Certain nerves, because of some peculiarity of location, exposure or function, are susceptible to irritation resulting in what is termed neuralgia. The lumbar plexus with its ramifications and connections principally through the ilioinguinal and iliohypogastric, are in direct contact with the entire urogenital tract, and often troubles ascribed definitely to ovaries or appendix may be due to tissue relaxation and visceral ptoses, diminished blood-pressure and vascular impoverishment or a hypersensitive urogenital tract. *Eighty per cent.* of women seen by physicians have floating kidney, which is but an index of tissue relaxation, and permanent cure by a year or two of physical culture and development is better than doubtful relief by fixation. *Too many women are operated on* when no pathologic changes are found, though real changes are frequent enough. The ilioinguinal region offers brilliant results to the conscientious application of suggestive therapeutics, and physical development does more than *surgery or* medicine in this class of cases, particularly in young and unmarried women, in whom a morbid mental tendency may have been created by too much misdirected treatment. This article is a plea for more simple measures, hygiene, elimination, proper support of the viscera, vibratory or other massage, electricity, or even if necessary sometimes the nerve-blocking alcohol treatment of Schlösser, and the *fostering of a corect* mental attitude in the patient.

DISCUSSION

Dr. J. H. Ford, Indianapolis: Many cases of obscure pelvic pain may be due to a relaxation of the sacroiliac joint, which Kellogg of Boston and Bland of Washington have demonstrated has more or less movement, following a wrench or injury. The pain may be severe in the interpelvic region, in the sciatic region or down the thigh. The diagnosis is determined, as well as relief afforded, by a supportive strapping of the pelvis by adhesive plaster.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Fifty-ninth Annual Session, held in Philadelphia, Sept. 27-30, 1909
(Continued from page 1323)

SYMPOSIUM: THE MUNICIPAL MANAGEMENT OF COMMUNICABLE DISEASE

The Rôle of Microzoa in the Causation and Transmission of Communicable Disease

Dr. Joseph McFarland, Philadelphia: Bacteria and other fungi maintain an indefinite existence under uniform conditions. The only known modification is entrance on a resting stage in the form of spores. These spores are able to grow and multiply when proper substratum is provided. With protozoan parasites the life history is more complex. In some cases parasites may be transplanted directly from the blood of one animal to another, but in most cases they pass indirectly through some other animal, or after transformation in the parasitic organism in the outer world. The patient and the infectious agents in his body are to be considered in most infectious (bacterial) diseases, but insect hosts and infectious agents in their bodies are also to be considered. Knowledge of the lattter group is but in its inception and made difficult by our inability to recognize many of the parasites because of small size or other peculiarities.

Etiologic Factors in Scarlet Fever

Dr. Jay F. Schamberg, Philadelphia: The streptococcus bears much the same relationship to scarlet fever that it does to smallpox. The influence of cutaneous burns and surgical operations under anesthesia are depressing factors increasing the susceptibility to scarlet fever. Most of the scarlatinoid eruptions occurring after burns represent the exanthem of scarlet fever. Such patients, even though they present an incomplete syndrome of the disease, should be perfectly isolated. Under certain conditions children may carry around in their throats the germs of scarlet fever and develop the disease only after the depression of the vital forces by a burn, surgical operation or other cause. There is *no proof* that infection is resident in the desquamating epithelium of scarlet fever; on the other hand, there is both clinical and experimental proof that infection resides in the discharge from the ears, nose and throat. The condition of these cavities may be *regarded, therefore,* as a safer criterion for the prolongation or cessation of isolation than the termination of the stage of desquamation.

Food Supplies Likely to Transmit Disease

Dr. M. B. Ahlborn, Wilkes-Barre: Concerning milk and milk products the most important prophylactic measures are education of the public regarding infection and the creation of public sentiment in favor of clean food supplies. There should be sensible sanitary legislation and its strict enforcement by trained sanitarians. There should also be supervision of all dairies, farms and cattle and of all employees on farms or in daries, and rigid inquiry made into the health of all cattle and employees handling milk. In cities there should be compulsory registration of all dairies at stated intervals, as to location, methods of handling products, and chemical and bacteriologic examinations should be made regularly. Regarding meat, fish and shellfish, supervision should be required of all slaughter-houses and carcasses of animals killed for food, with the regulation of the health of those engaged in the production of meat products. Rigid attention should be given to cleanliness in storage and shipping. Sale should be prevented of fish and shellfish taken from contaminated waters. No human manure should be used on truck farms or contaminated water employed in the washing of vegetables and fruits. All vegetables and fruits should be protected from dust and insects when exposed for sale.

What Shall We Do About Trachoma?

DR. CLARENCE P. FRANKLIN, Philadelphia: Trachoma was originally an alien disease, but is now acclimated. It interferes with the "workability" of the eyes of adults and children, and thus is a menace to the public welfare. Interest should be aroused to accomplish its elimination. There is need of more active interference with the course of the disease in Pennsylvania, of trachoma hospitals and trachoma schoolhouses in this state as are successfully maintained abroad.

Quarantine and Isolation

DR. WILLIAM M. WELCH, Philadelphia, explained the object of isolation and enumerated the diseases requiring the enforcement of the measure. He emphasized the importance of the procedure and described effective methods. He also considered restrictive measures applicable to the well members of the household. The duration of isolation must vary, he said, in different communicable diseases.

Disinfection

DR. JAMES J. QUINEY, Easton, said that many disinfectants generally employed are of questionable value. There should be careful disinfection of eating utensils, medicine and drinking glasses, clothing, bedding, etc. The cleansing of floors, woodwork and furniture should be thorough. No cuspidors should be allowed. The paper deals further with the disinfection of discharges from nose and throat, of excreta, water used for bathing purposes, of the patient and nurse, of room and furnishing, the preparation of the room for disinfection, and with the materials used for fumigation.

SYMPOSIUM: STATE APPROPRIATIONS TO HOSPITALS

What Pennsylvania Is Doing

DR. JOHN B. ROBERTS, Philadelphia, gave a short history of the origin of the present system of making appropriations to hospitals not under state control by the legislature of Pennsylvania. He mentioned the benefit that had come from these appropriations in giving all sections of the State Hospital facilities with the accompanying valuable training of nurses and doctors. He seemed to think that these advantages were offset by the manner in which the appropriations were granted by the legislature without any definite restrictions such as the law supposed would be thrown around the appropriation system by the investigations made by the board of public charities. He showed that hospitals were granted large sums for maintenance even before the institutions were built in some instances, and that in some cases the amount given for buildings and maintenance was out of proportion to the small amount raised by private subscriptions. The suggestion was made that the system led to an actual plunder of the public treasury.

State Appropriations to Hospitals: What Other States Are Doing

DR. CHARLES MCINTIRE, Easton, Pa.: This paper was planned to give a comprehensive view of the relation sustained by the various states to hospitals within their borders but not directly under state control. With the exception of Arkansas and Arizona, from which no information was received, for the purpose of this paper, the states of the Union could be tabulated in three divisions: 1. Those which are forbidden by law to make appropriations to institutions not entirely under state control. 2. Those which, while there is no legal prohibition, do not make such appropriations. 3. Those which are making such appropriations. As in the practical outcome there is no difference between the first and the second class these two divisions are included in one list. According to the information furnished, thirty-four states in all make no appropriations. In the remaining list are included those that make appropriations under any conditions whatsoever. As these conditions vary, the acompanying statements are interesting: Of Connecticut the state controller writes: "It has been the practice of this state for many years to appropriate toward the maintenance, and in some instances toward the building, of hospitals under private control in various parts of the state."

Kansas makes appropriations, apparently without conditions.

Louisiana "partially" supports two hospitals; one at New Orleans and one at Shreveport.

Maine makes appropriations. My correspondent writes: "You ask, 'What are the principles governing the appropriations and are there any means of oversight?' The principle in all these things is to get all that is possible by any means, fair or foul. 'Log rolling' is everywhere. The state has control over the two insane hospitals; the other institutions are conducted by boards which are practically self-perpetuating. Some of the organizations which get appropriations are absolutely private affairs."

Of Mississippi, the secretary to the governor writes: "There are three charity hospitals in this state to which appropriations are made by the legislature on condition that a fixed amount of money shall be donated by the county and municipality in which they are located. These institutions were not originally organized by the state, but for years have been receiving state aid to the extent mentioned."

From the attorney general of New Mexico I learn that the territory does not maintain any public hospitals, and has therefore made it a practice in the past few years to make appropriations to the various charitable hospitals in the territory. The legislature, however, is about to strike out all the appropriations to charitable institutions with the exception of two orphan asylums. . . . However, there is no constitutional provision in this territory prohibiting such action.

The Albany Hospital in the state of New York is the only hospital in the state that receives an appropriation directly from the state treasury, and this is to pay for the care of employees of the state who may become injured or sick while on duty at the capitol. The secretary of the State Board of Charities of New York writes that while most of the cities and counties, as provided by the constitution, do pay sums of money to hospitals, it is in the shape of *per capita* for services and not the appropriation of a gross sum.

Rhode Island makes appropriations to various "charities," among which are enumerated some hospitals.

While I have included Vermont among the states making no appropriations, to be literally accurate, I should report that from 1834 until 1888, the only hospital for the insane in the state was one founded by private bequests. This institution, in return for special privileges granted, received small appropriations from time to time, amounting, probably, to about $35,000 in sixty-five years. This money is a lien on the property should it ever cease to be used for an insane hospital.

Advantages of the Pennsylvania System

DR. HORACE G. MCCORMICK, Williamsport: The state is out of debt, she has ample means, the taxes she receives and the money she distributes come from those who are amply able to pay, and what better use, both from the standpoint of humanity and as a financial investment, can she make than is shown by her appropriations to the hospitals of the state? Have any of her appropriations ever been more carefully used, have any shown less graft, have any done more for the relief of the poor and the betterment of humanity than those given to the hospitals of the state? The appropriations made by the legislature each two years, at least to the hospitals outside of the two great cities of this commonwealth, are probably as fairly distributed as could be done by any system that could be devised. The people have put their stamp of approval on the system of the state, giving them all in its power, and it never will be otherwise.

Objections to the Pennsylvania Method

DR. LAWRENCE F. FLICK, Philadelphia: The whole subject of state appropriations to hospitals as practiced in Pennsylvania can be categorically stated as follows:

1. State appropriations to incorporated non-sectarian hospitals are constitutional.
2. The incorporated hospital is the best channel for expending public money for the sick poor.
3. The state hospital was introduced in 1845.
4. A state department of charities for the control of all the charities of the commonwealth was created in 1869.
5. Our constitution and laws contemplated the administration of our charities by incorporated bodies under the supervision of the state board of charities.
6. In the spirit of our laws no appropriations should be made for charitable purposes except upon the recommendation of the state board of charities.
7. Practical politics have militated against the proper application of public charity.
8. Appropriations to hospitals have become a corrupting influence in politics.
9. The state department of health's assumption of hospital and eleemosynary functions was a further inroad of practical politics upon hospital work and is illegal and unconstitutional.
10. The objections to the Pennsylvania *method* of *state* appropriations to hospitals are in the politics which have crept into these appropriations and in the disregard for our constitution and law.
11. The remedy is the exclusion of politics from public charity and the strict enforcement of our laws bearing on it.
12. State appropriations should be made to all hospitals on the basis of private resources and the number of patients treated.

Suggested Improvements

Dr. William L. Estes, Bethlehem: 1. State supported hospitals should carefully guard against imposture and assistance unworthily bestowed, in order to prevent the pauperization of communities. No efficient system has yet been devised to accomplish this end. 2. It is recommended that every person admitted to the hospital shall be charged a fixed definite rate, according to the accommodations selected. Those demanding free treatment, who enter the charity wards, should be charged for treatment, an amount necessary to cover the expense of this treatment. If the person so charged can prove that he is absolutely not able to pay for treatment the state should pay for him. The burden of proof should always be on the patient. 3. Hospitals should use the data in regard to the number of days in the hospital each free patient has spent, and the actual cost, plus a moderate percentage to cover the repairs and maintenance of the buildings, as a basis for soliciting state aid. 4. The state has a right to demand economy and efficiency in the treatment of its wards. The multiplication of hospitals beyond the needs of the communities is to be deplored, because many small hospitals cost much more than a few larger ones to run, and, as a rule, are not as efficiently conducted. 5. All state assisted hospitals ought to be made a part of the educational system of the state. The clinical material of these hospitals ought to be made available for the instruction of the physicians of the community. 6. Some suggestion as to how the cases in hospitals may be used for instructing physicians.

Discussion on State Aid to Hospitals

Dr. Henry W. Cattell, Philadelphia: There is great difficulty in properly discussing the question of state appropriations to hospitals without making the issue a political one. Money appropriated to hospitals under the conditions as they exist in Pennsylvania to-day must *too often* be considered as a direct bribe for political influence. The recipe for getting an appropriation to a hospital in Pennsylvania to-day is somewhat as follows: Devote from 10 to 20 per cent. of appropriation to political purposes and charge it up to local expenses. Have plenty of private rooms and give 50 per cent. of these rooms to the politicians and their friends and permit the other 50 per cent. to be occupied by the pay patients exclusive of the medical and surgical staff of the hospital that receives the appropriation. The time has arrived in the Commonwealth of Pennsylvania to separate distinctly the charitable institution from that managed with an ulterior object in view. It is an absurdity that there are six medical schools in the city of Philadelphia, and one of the solutions in this problem of state appropriations to hospitals lies in reducing at once the number of medical schools in this city from six to three.

Dr. C. E. Thompson, Scranton: It is not the experience in our part of the state that, as claimed by Dr. McCormick, the hospitals receiving state aid are valuable as schools for physicians and nurses. Against his claim that we must have these hospitals supported by the state in order that we should have professional nurses, if he will come to our community I will show him a hundred nurses graduated and now in practice who came from schools that never received any state aid. He speaks of improvements in the non-admission of patients who can afford to pay in our hospitals. There is no improvement in our end of the state. In fact, it is getting worse; and, as to the reduction of graft, I don't think that the state of Pennsylvania has ever taken up the reduction of graft as a specialty. We all know these political evils and we are here to try to correct them, and I should like to make a recommendation that Dr. Estes be instructed to make a draft of his recommendations and bring it before our house of delegates. (The motion was carried.)

(To be continued)

AMERICAN ROENTGEN RAY SOCIETY

Tenth Annual Meeting, held at Atlantic City, September 23-25

(Concluded from page 1321)

Roentgen Diagnosis of Pulmonary Lesions

Dr. Charles Lester Leonard, Philadelphia: The Roentgen method of examination of the chest is of great value as an adjunct to physical diagnosis, particularly in early deep-seated lesions, peribronchial infiltrations and bronchial adenitis. In the advanced cases it adds an element of greater accuracy and detail in localizing the affected area; it corroborates the physical signs and is at all times a mechanical method of registering observations which can be compared with others later. Not infrequently, deeply situated areas of consolidation and cavities are seen in the skiagraph that have escaped other methods of examination. Besides the alterations in the lungs and pleura produced by tuberculosis, the Roentgen ray discloses pericardial effusions and thickenings of all kinds. Other features seen are the relative height of the diaphragm on both sides, the relations of the heart and larger blood-vessels, and calcification of the costosternal cartilages.

DISCUSSION

Dr. P. M. Hickey, Detroit: I wish to sound a note of warning with reference to interpreting shadows around the root of the lung as being due to enlarged glands when in reality they are the result of a chronic inflammation around the bronchi. In two cases I made the diagnosis of tuberculosis, but the tuberculin test failed to confirm the diagnosis.

Dr. L. G. Cole, New York: I agree with Dr. Hickey, but nevertheless I am convinced of the superiority of the Roentgen ray in diagnosing early incipient cases of tuberculosis. The radiogram registers pathologic changes long before they can be detected by physical examination. The mottled appearance of the lungs is absolutely characteristic of tuberculosis, no matter where it is found.

Dr. K. Dunham, Cincinnati: We must not lose sight of the fact that the tuberculin test is the most valuable means of diagnosis in tuberculosis and that the Roentgen ray is next.

Dr. Arthur Holding, Albany: The important feature of roentgenography of the chest is not the making of the diagnosis, but the determination of the pathologic condition present. A skiagraph should be made of both sides of the chest for purposes of comparison.

Dr. George C. Johnston, Pittsburg: Not infrequently a few small doses of potassium iodid, about three grains three times a day, produce sufficient local congestion to facilitate materially the diagnosis of tuberculosis. Care must also be taken not to mistake syphilis of the lung for tuberculosis.

Dr. K. Dunham: Tuberculin has the *same effect* in these cases as has potassium iodid.

Roentgen-Ray Diagnosis of Diseases of Bone

Dr. W. H. Dieffenbach, New York: I have made a special study of bone lesions caused by gonorrhea, and have found certain lesions which I believe are characteristic of the condition. These are (1) deformity and enlargement of joints; (2) diminution of shadow involving the peripheral portion of all bones of the affected joints (3) small sclerosed intraosseous areas in the shaft or epiphysis, the so-called Carleton's spots.

DISCUSSION

Dr. Percy Brown, Boston: I believe Dr. Dieffenbach is in error in this matter, because the changes in bone enumerated by him as being characteristic of gonorrhea are found in nearly every case of infectious disease.

Dr. F. H. Baetjer, Baltimore: I have found that in gonorrhea the bone is never attacked until after the cartilage has been eroded. The disease never attacks the diaphysis.

Technic in Calculus Diagnosis

Dr. A. L. Gray, Richmond, Va.: In this work I prefer to use a cone or cylinder because it obviates a source of error that may present itself in foci of calcification in the lower costal cartilages and it is an easy method of directing the rays through the kidneys to the plate. By forcing the back into close contact with the plate, the sharpness of the calculus shadow is increased. I always make four plates, one of each kidney, one embracing the ureters well into the true pelvis, and the fourth of the true pelvis, including the entire surface of the symphysis pubis. The kidney and ureter plates are made with the patient in the dorsal position, the head low and the thighs well-flexed on the pelvis; the semi-sitting posture is the best for making a plate of the pelvis. I wish to call attention to soiling the plate by sweat, because a sweat stain cannot be differentiated from a calculus shadow. I protect my plates with rubber dam or thin celluloid.

Speed Mania in Radiography

Dr. L. G. Cole, New York: The disadvantage of making extremely rapid exposures is that it spoils many good tubes; however, absence of motion is essential to good detail. In chest and abdominal work the exposure should not exceed the time the patient can hold the breath. Detail and not speed is the object to be sought after in radiography.

DISCUSSION

Dr. P. M. Hickey, Detroit: Speed is not always necessary, but no hard and fast rule can be laid down except that as much speed should be used as is needed to get detail. The smashing of tubes is a minor consideration, and it is up to the manufacturers to overcome this by making better tubes. The tubes in use to-day are far better than those employed five years ago.

Dr. George E. Pfahler, Philadelphia: In order to secure a skiagraph of a moving part of the body, it must be made in a period of time that is too short for that part to move in. If detail is not essential there is no necessity for speed, but unfortunately detail is the one thing needed in radiography.

Dr. E. W. Caldwell, New York: When a satisfactory appliance to produce a satisfactory current for the proper excitation of tubes is devised, the speed problem will to a large extent disappear, and with it many of the difficulties of the tube manufacturer. An apparatus which will supply a tube with one hundred milliamperes will do away with the necessity for high speed.

X-Ray Work in Hospitals

Dr. Rollin H. Stevens, Detroit: A large number of hospitals are equipped with suitable radiographic apparatus, owned either by the hospital, the staff, or the radiographer, usually the former. Some of the hospitals pay the radiographer a salary, others a percentage; and still others divide the fees. Inquiry has convinced me that every modern hospital is alive to the advantages of a Roentgen-ray equipment, not only for diagnosis but for treatment. I find that many hospitals keep careful records and some employ a staff of assistants to do this work. No hospital aiming to do scientific work can afford to be without such an equipment.

Use of Roentgen Ray in Goiter

Dr. Carl Beck, New York: I have employed the Roentgen ray in treatment of all forms of goiter, with varying success. In exophthalmic goiter I favor the combination method, that is, removal of a portion of the gland followed by Roentgen irradiation. In advanced cases in which immediate operation is contraindicated the ray should be employed until the condition of the patient has been improved sufficiently to permit of operation. I have employed the combination treatment in fourteen cases, a cure resulting in thirteen.

Tuberculous Cervical Glands

Dr. K. Dunham, Cincinnati: In thirteen cases which I have studied I found an enlargement of the mediastinal glands, which I believe proves conclusively the fallacy of attempting a radical removal of the cervical glands in the hope of eradicating the disease. I find that the combined use of mercurial injections and Roentgen irradiation of the affected glands is the best treatment. Surgery should be reserved for those cases in which the glands are broken down and sinuses are present.

DISCUSSION

Dr. Arthur Holding, Albany: I am convinced that the Roentgen ray is possessed of curative powers, almost specific in character, in tuberculous adenitis. When the lesions are small I use the high-frequency vacuum electrode first; in the more advanced cases I use the ray at once. When the glands break down they should be opened and then rayed.

Roentgen Ray Dermatitis

Dr. M. K. Kassabian, Philadelphia: This dermatitis may be either acute or accidental, the dermatitis of the patient, or chronic, the dermatitis of the operator. Both now occur rarely, owing to improved apparatus and greater care in its use. Only the most thorough protection against exposure to the ray gives the operator any degree of safety. I never use a fluoroscope and I am never exposed to the ray to the slightest degree. The operator's dermatitis usually comes on slowly and passes through stages of redness, dryness, itching, ulceration and pain. The most effective treatment in the acute cases is hot normal salt solution. In the chronic cases, exposure to the ray and trauma of any kind should be avoided, the affected parts should be anointed with lanolin, the hands kept warm, gloves worn, no soap used, the hands immersed frequently in hot water, fissures touched with a 5 per cent. argyrol solution. A posterior digital splint will hasten the healing of a fissure, but rest, absolute rest, is the most essential factor in the treatment. Warty growths must be excised and the defect covered with a skin graft.

Roentgen Ray in Carcinoma of the Uterus

Mr. H. W. Dachtler, Toledo, Ohio: I have had good results from the use of the Roentgen ray following operation for carcinoma of the uterus, but sufficient time has not yet elapsed to permit of drawing conclusions as to the effectiveness of the treatment. I employ a short, wide tubular speculum, and a tube of small diameter, so that the rays are brought as near the seat of trouble as possible. The treatment is begun the second day after operation, and is continued daily during the patient's stay in the hospital.

Measurement of the Roentgen Ray

Dr. C. M. Peabody, South Orange, N. J.: The fundamental principles involved in my method of measurement are based on known physical laws, and the method is easily applicable by any one under any circumstances. By making a series of exposures so as to obtain plates of graduated density, various units of work are obtained, and by bearing in mind that "the work done by any force varies with the time through which it acts," and "that the work done by a given light varies inversely as the square of the distance from the source of light," and "that the work done by any *x*-light varies with the quantity of current passing in the tube, other conditions remaining constant," a working formula may be evolved.

Book Notices

CONSTIPATION AND INTESTINAL OBSTRUCTION. By Samuel Goodwin Gant, M.D., LL.D., Professor of Diseases of the Rectum and Anus in the New York Post-Graduate Medical School and Hospital. Cloth. Pp. 559, with illustrations. Price, $6. Philadelphia: W. B. Saunders, Co., 1909.

This work begins with a preliminary section on anatomy and physiology, after which etiology is extensively discussed to the amount of 70 pages, the greater part of which is taken up by mechanical (obstructive or surgical) causes. Symptoms, consequences and diagnosis are next considered to the extent of 77 pages. The remainder of the volume, over 300 pages, is taken up with treatment. The exciting causes given have been pointed out many times—neglect of parental supervision, false modesty, abuse of purgative drugs, etc. Visceral ptosis is probably given too prominent a place in the etiology, and some aspects of the former seem entirely outside the scope of the work.

Coming now to the treatment, while the routine use of drugs is not advised, yet, for those who prefer their use, an account of the various agents is followed by a rather lengthy selection of formulas. The non-medicinal treatment is considered at great length—massage, vibration, psychotherapy, diet, etc. Included in the surgical treatment are descriptions of various stock operations, enterectomy, end-to-end anastomosis, and so on, which might very well have been omitted, with references to any modern operative surgery for details of the technic. This, of course, does not apply to Dr. Gant's personal technic and modifications. Again, more than one of the illustrations—for example, that of a nurse wringing out fomentations, and pictures of Davidson's syringe and similar devices—add nothing to the text. Moreover, a great deal of the apparatus alluded to will scarcely be found save in the armamentarium of the specialist.

The work as a whole, however, impresses us rather favorably and a perusal of it will result in the acquisition of much interesting information concerning this wide-spread ailment.

DIET IN HEALTH AND DISEASE. By Julius Friedenwald, M.D., Professor of Gastro-Enterology in the College of Physicians and Surgeons, Baltimore, and John Ruhräh, M.D., Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. Cloth. Pp. 765. Edition 3. Price, $4 net. Philadelphia: W. B. Saunders Co., 1909.

The revisions and additions to be found in the third edition of this work have increased its value and broadened its scope. A number of useful tables have been added, one of the most notable being Winton's list, giving the composition of diabetic foods, in which many of the so-called diabetic flours on the market are shown to be dangerously rich in carbohydrates. The chapters dealing with alcohol and milk have been practically rewritten and a brief description of the less complicated methods of detecting preservatives and adulterations in food has been added. In dealing with a subject that, at present, is receiving more than usual attention, viz., the use of chemical preservatives in foods, other than the commoner ones of sugar, salt, vinegar and wood-smoke, the authors take a conservative stand. Admitting that the question of the actual effect of various preservatives on the human body is still an unsettled one they assert: "It may safely be stated that the addition of any chemical preservative to food is undesirable." In fact, the general tone of the book is one of conservatism; the authors ride no dietetic hobbies and the result is a work that is eminently practical in scope whether it be used by the practitioner or the medical student.

REPORT OF THE BOARD OF TRUSTEES "COMMISSIONERS OF WATER-WORKS" OF CINCINNATI, OHIO. By Geo. H. Benzenberg, Chief Engineer. 1909. Cloth. Pp. 267, with illustrations.

The city of Cincinnati was one of the first of the large cities in this country to install complete water-purification works. Lime and sulphate of iron are used as coagulants. The construction of the plant was undertaken only after careful investigation into the local conditions, and the work throughout has been supervised by some of the leading American sanitary experts. The present report gives an admirable history of the enterprise, including a summary of the experiments on filtration which were discussed in full in a previous publication. A section on the operation of the plant for the year 1908 is given, in which we learn that over 50 per cent. of tests made with 100 c.c. of filtered water were negative for *Bacillus coli*. The cost of filtration is stated at $4.40 per million gallons. The report is beautifully illustrated with photographs and line drawings.

INBORN ERRORS OF METABOLISM: The Croonian Lectures Delivered Before the Royal College of Physicians of London, in June, 1908. By Archibald E. Garrod, D.M., M.A., Fellow of the Royal College of Physicians. Cloth. Pp. 168. Price, $1.35. New York: Oxford University Press, 1909.

A year ago Garrod delivered a series of lectures before the Royal College of Physicians of London on the above topic, which were shortly afterward published in the *Lancet*. They have now been somewhat amplified, brought up to date, and published in the form of a small book, which makes them much more accessible and useful to many readers. The known conditions which correspond to the title are albinism, alkaptonuria, cystinuria and pentosuria, and after an introductory chapter on the general relations of heredity to metabolic variations, these four subjects are considered at length. In all respects the discussions are interesting, authentic and readable. They bring the knowledge of the subject well up to date, and the chapters on alkaptonuria and cystinuria probably represent the best summary of these subjects to be found anywhere. Albinism is not discussed to as great length as it might be, and it would seem that retinitis pigmentosa, with its striking relation to parental consanguinity, should have been considered. Any physician who wishes a pleasant bit of reading which will give him an insight into the way chemical methods are making progress in medical problems, will find much to interest and please him in this little book, while every progressive physician will value it for its thorough consideration of four obscure metabolic abnormalities.

A TEXT-BOOK OF THE DISEASES OF THE EAR. By Prof. Dr. Adam Politzer, [illegible] sor of Aural Therapeutics in University of [illegible] at the Personal Request of the Author, a [illegible] J. Ballin, Ph.B., M.D., Assistant Surgeon, [illegible] and Aural Institute, and Clarence L. Heller, [illegible] Cloth. Pp. 892, with 337 original illustrations. Price, $8.00. Philadelphia: Lea & Febiger, 1909.

Since the appearance of the last edition of Professor Politzer's "Diseases of the Ear" six years ago, most marked advancement in otology has been made in the physiology and pathology of the internal ear. As a result, new operative procedures have been pointed out and made possible in that region. During the same period intracranial lesions of aural origin have been rendered more accessible by improved operative methods. The new edition of this standard work gives the results of the investigations of Politzer and his followers in these new fields, as well as a revision of those subjects made necessary by the recent advancement in the pathology and therapeutics of aural affections in general. The addition of this new material again places a work of inestimable value in the hands of students of otology.

GENETIC PSYCHOLOGY: An [illegible] bjective and Genetic View of Intelligence. By [illegible] B.S. M.Ph., Author of "Fundamentals of [illegible] Pp. 373. Price $1.25. New York: Macmillan Company, 1909.

As an invitation—Mr. Kirkpatrick calls it an "introduction"—to the further and deeper study of modern psychology, this little book is deserving of commendation. Beyond all doubt it is true that "the theory of evolution has completely revolutionized the biologic sciences and is now making similar changes in psychology, the science dealing with the highest form of life, that of consciousness;" but none the less true is it that we are yet very far from being able to apply all the observations recorded in the biologic sciences as explanations of all the phenomena noted in the mental sciences. It is on this point that nearly all of the books of this class become unreliable. Not being large enough to present all sides of the questions at issue, including the data both for and against the theories of mind, they become too dogmatic in assertion, make assumptions not fully warranted by the facts in hand, and lead the careless and little-read student to accept as the final word of science what is merely the one-sided view of an over-enthusiastic writer.

The earlier chapters of the book, devoted to a discussion of behavior and its structural basis, to types of animal behavior, to complex behavior characteristic of species, to behavior of individuals, and to the structures concerned in complex behavior and in ideation, though brief and compressed, are admirable, so far as they go, in summarizing in general the observations made in the experimental laboratory.

The chapters in which there is a consideration of consciousness, of specific conscious states, and of types of adaptive activity or intelligence are far less satisfactory. Here too often Mr. Kirkpatrick plays on words or assumes that the mere description, in scientific jargon, of commonly observed phenomena is equivalent to explanation. Occasionally he contradicts himself. These faults, however, are not at all uncommon among compilers of psychologic handbooks, who are unduly impressed with the inductive methods of the laboratory. Space does not permit of more than one illustration. By attaching a novel meaning to the word "intelligence," so as to have it synonymous with "the adaptation of means to ends," and thereby conferring on it a breadth to include unconscious as well as conscious processes, chemical, physiologic and physical, Mr. Kirkpatrick concludes that man posseses four kinds of "intelligence," physiologic, sensory-motor, representative and conceptual, all of which differ from one another in degree more than in kind, all being dependent on like neural elements and processes. Both the liver and the brain functionate, of course, in the line of adapting means to an end; but to call the force behind these functions "intelligence" it thereby assumes that the functions are essentially the same, is pushing the logic of analogy rather far. A mere play on the word intelligence is made to take the place of scientific proof. The use of the term "growth" in connection with the processes of crystallization and of protoplasmic development does not establish the similarity of the processes.

The best chapter in the book is that entitled "Types of Learning Activity: Nature of Learning." It is full of valuable suggestions, showing Mr. Kirkpatrick's familiarity with the science of practical pedagogics.

The final chapter is a summary of Mr. Kirkpatrick's own particular psycho-physiologic theories and their use in accounting for man's autogenetic and phylogenetic progress.

A Treatise on the Principles and Practice of Medicine. By Arthur R. Edwards, A.M., M.D., Professor of the Principles and Practice of Medicine and of Clinical Medicine and Dean of the Faculty in the Northwestern University Medical School, Chicago. Second Edition. Cloth. Pp. 1212, with 100 engravings and 21 plates. Price, $5.50. New York and Philadelphia: Lea & Febiger, 1909.

A new edition of a book frequently means simply a new impression with no alterations whatever. With the work before us, however, it is different. We quote from the preface: "Particular attention has been given to therapeutic details in accordance with the recent awakening of the profession to the importance of logical treatment; numerous new preparations and modified names and dosages, particularly for children, are explicitly specified. There are practically new chapters on the arrhythmias and other cardiac neuroses, tropical splenomegaly and various other tropical affections. Due consideration has been given to the meningitis serum of Flexner and Jobling, Strong's work on amebic dysentery, blood cultures in typhoid and other bacteriemias, the "carriers of infection," the recent epidemics of meningitis and poliomyelitis, the accumulating evidence in favor of the spirochete as the cause of syphilis, and the recent status of tuberculin in its therapeutic application and in its various diagnostic uses, as the ocular-reaction and von Pirquet's test.

Thus there has been no labor spared on the part of the author, or expense on the part of the publishers to improve the book in every particular, and especially to bring it thoroughly up to date. The fact that a new edition has been demanded within two years after its initial issue does not always mean that the book is a success, but this is undoubtedly the case in this instance. Edwards' "Practice" has deservedly taken its place as one of the standard text-books on practice, and it will continue to hold this place if future editions are as honestly and conscientiously revised as this one has been.

It is to be regretted that there is no analytical table of contents in the front of the book. The index is an elaborate and satisfactory one, but an analytical summary in such a work as this is of as much importance as the index.

Clinical Diagnosis and Treatment of Disorders of the Bladder, with Technique of Cystoscopy. By Follen Cabot, M.D., Professor of Genito-Urinary Diseases, Post-Graduate Medical School, New York. Cloth. Pp. 224, with illustrations. Price, $2.00. New York: E. B. Treat & Co., 1909.

The clinical diagnosis of disorders of the urinary bladder, with especial reference to the use of the cystoscope, the technic of cystoscopy, and the treatment of disorders of the bladder are the chief subjects of Dr. Cabot's little book. It takes up systematically case records; management of the patient; anatomy of the genitourinary tract; urinalysis (a short chapter); a description of the methods of examining the bladder and the segregation of the urine; the technic of and indications and contraindications for cystoscopy; the causes, diagnosis and treatment of cystitis, and the diagnosis and treatment of senile prostatic hypertrophy. The book does not attempt to cover the entire subject, but is in a great measure a record of personal experience, set forth clearly and plainly, by a man who is evidently a practical teacher.

Diseases of the Pharynx and Larynx. By Dr. E. J. Moure, Surgeon in Charge of the Nose, Ear and Throat Department of the Faculty of Medicine, Bordeaux. Translated and Adapted by J. Malcolm Farquharson, M.B., F.R.C.P., Lecturer on Diseases of the Nose, Ear and Throat in the School of Medicine of the Royal College, Edinburgh. Cloth. Pp. 403, with illustrations. Price, $4. New York: Rebman Co., 1909.

The experience and knowledge of the distinguished author of this work have eminently fitted him to write a treatise on the diseases of the pharynx and larynx; he has condensed a surprising amount of information into a comparatively small volume. The profuse illustrations, both colored and in black and white, are all good and many of them admirable; they are most instructive because of their exactness.

The book would have gained in power to instruct had there been less attempt at brevity in its writing, for the description often suffers in clearness on account of the effort to employ a laconic style. Logical and connected, yet concise, expression implies a rare command of language; and this may exist in the original French version of this book, but is certainly not a quality of the translation. Some passages are so confused as to be quite unintelligible. A representative example is the following, referring to laryngeal paralysis of central origin: "Along with Lannois, the author admits that vocal disturbances are most frequent in labio-glosso-laryngeal paralysis. Charcot has described a defect of adduction of the cords which explained their aphony. Laryngoscopic examination alone determines the nature of the lesion, which produces vocal disturbances. Here it is a comparatively trivial symptom, but otherwise in the case where the two vocal cords are fixed in the mesial line, direct examination permits of therapeutic deductions being drawn." This disconnected and incoherent passage is so meaningless that it could hardly instruct the general practitioner, for whom the book is supposed to be designed. Even one familiar with the nervous affections of the larynx cannot understand what is meant.

A similar paragraph, referring to the vagospinal paralysis, reads: "On laryngoscopic investigation the vocal cord appears as in recurrent lesions. However, the pneumogastric being a mixed nerve, its compression determines immobilization of the two cords almost in the middle line, the one being paralyzed and the other in reflex contraction." This passage is also quite confused, and a condition is merely alluded to which requires a logical explanation for the student's sake. By "recurrent lesions" in this paragraph the translator, of course, means lesions of the recurrent laryngeal nerve. In ordinary English the expression "recurrent lesions," however, would imply returning lesions, and the expression would be so understood by readers not familiar with the subject. In other parts of the book paralysis of the recurrent laryngeal nerve is spoken of as "recurrent paralysis"—an equally misleading use of the word "recurrent."

Those especially versed in laryngology and the diseases of the pharynx can grasp the author's meaning in the many confused passages of the translation; but the work cannot be recommended as an introductory text-book. It is to be regretted that the translation of this book, which shows in part the excellence the whole might possess, should have such serious defects.

Medicolegal

Courts Cognizant of Accuracy of X-Ray Photographs—Damages for Injuries

The Court of Civil Appeals of Texas says that in Houston & Texas Central Railroad Co. vs. Shapard (118 S. W. R. 596), a personal injury case, objection was made to the admission in evidence of photographs of the bones of the plaintiff's injured leg taken with an *x*-ray instrument, the burden of the objection seeming to be that, without cutting away the intervening flesh, skin, etc., it was impossible to tell whether the pictures correctly represented the condition of the injured bones. But the court holds that there was no error in admitting the photographs in evidence, in connection with the testimony of a physician as to the character and use of the *x*-ray instrument and the manner in which the photographs were taken, it being shown that the instrument used was a correct one of the kind and had been frequently used by the witness. It would be strange, the court, says, if in the trial of cases in the courts use could not be made of facts elicited by means of a process the usefulness and absolute accuracy of which has been so completely demonstrated as have been photographic views of the bones of a living body by means of the *x*-ray. When properly taken, as these views were shown to have been, it is a matter of such common knowledge that they accurately represent what they purport to show that even courts may take cognizance of the fact.

The plaintiff was a railway fireman, 27 years of age, when injured. The evidence showed that both bones of the leg were broken between the knee and the ankle, that one of the bones had never properly united; and that in consequence the foot was turned in, interfering with his walking. While in the hospital, about a dozen small pieces of the bone of the leg were taken out. Also, according to his testimony, flames from burning oil reached him at the time of the accident and set his clothing on fire, and his legs, feet and some parts of his body were severely burned. He endured very great physical suffering for several months, from the burns and from the wounds on his broken leg, which required some time to heal. The jury allowed him $25,000 damages, but the court thinks $17,500 sufficient.

No Extra Compensation for Disinfecting

The Supreme Court of Michigan says that the case of Tabor vs. Board of Supervisors of Berrien County (120 N. W. R. 588) was based on a city health officer's claim for disinfecting and fumigating houses in which were or had been contagious and dangerous communicable diseases, smallpox, typhoid fever, scarlet fever, consumption, diphtheria, measles and pneumonia. The board of supervisors refused to allow the claim. It contended that the services rendered were the ordinary services required of a health officer by Section 4460 of the Compiled Laws of Michigan, which were compensated by the salary which it was conceded was provided for the claimant. The Supreme Court thinks that the board's position was well taken. Section 4460 is Section 1 of Act No. 137 of the Public Acts of Michigan of 1883, entitled "An act to specify certain duties of health officers and provide for compensation therefor, in townships, cities and villages where the health officer is not otherwise instructed by the local board of health." Section 4460 specifies the duties to be performed. The same section makes it the duty of the health officer "to disinfect rooms, clothing and premises and all articles likely to be infected before allowing their use by persons other than those in isolation." Section 4462—Section 3 of the act—provides that: "In the fulfillment of the requirements of this act, the health officer, unless other provision shall have been made in accordance with law, shall be entitled to receive from the township, city or village of which he is health officer, compensation at the rate of not less than two dollars per day," etc. It was the plainly expressed object of the statute to specify the health officer's duties and to provide the compensation for the specified duties. The service performed by the claimant was in discharge of a clearly specified duty, and the compensation therefor was provided for in Section 4462, or the provision for a salary "made in accordance with law."

Illegal Physical Examination of Defendant in Rape Case

The Supreme Court of Missouri, Division No. 2, says, in the rape case of State vs. Newcomb (119 S. W. R. 405), where there was evidence that the prosecuting witness had been found afflicted with gonorrhea, that the defendant, while in custody and charged with the crime of rape, and when without counsel, was ordered by the justice of the peace, at the demand of the prosecuting attorney, to submit to a physical examination of his privates by a physician. He was taken into a room of the courthouse, and in the presence of the sheriff was examined by a physician, both of whom testified as to the result of that examination, and as to what they saw during that examination and what they said to him. It was insisted that this was flagrant error and was a conspicuous violation of the constitutional right of the defendant to be exempt from testifying against himself. Some effort was made to show, on the other hand, that the defendant voluntarily consented to this violation of his person, but the court thinks that it was apparent that he simply submitted because he thought he was compelled to do so. When it is considered that he was at the time in custody for this very crime; that the prosecuting attorney demanded an order from the justice for this examination; that the sheriff took the defendant into a private room for the purpose of the examination—it is not strange that the latter thought he was compelled to submit. It is idle to talk of his having consented to this violation of his person. As the court reads the record, he had no option in the matter. The salutary provision of the statute would seem to have been overlooked. The court thinks that all of this testimony of the physician and the sheriff as to this examination should have been excluded. This testimony was incompetent and inadmissible and violative of the defendant's constitutional right not to be compelled to testify against himself. Furthermore, the court holds that, without regard to the legality of the examination, there can be no doubt but that it was error to permit the physician to detail to the jury what he said to the defendant during said examination.

Libel in Unauthorized Testimonial—Representing Physician as Advertising

The Supreme Court of the United States says, in reversing a judgment directing a verdict for the defendant in the libel case of Peck vs. Chicago Tribune Co. (29 S. C. R. 554), that the libel alleged was found in an advertisement printed in the defendant's newspaper, which read: "Nurse and Patients Praise Duffy's. Mrs. A. Schuman, One of Chicago's Most Capable and Experienced Nurses, Pays an Eloquent Tribute to the Great Invigorating, Life-Giving, and Curative Properties of Duffy's Pure Malt Whisky." Then followed a portrait of the plaintiff, with the words, "Mrs. A. Schuman," under it. Then in quotation marks, "After years of constant use of your Pure Malt Whisky, both by myself and as given to patients in my capacity as nurse, I have no hesitation in recommending it as the very best tonic and stimulant for all local and run-down conditions," etc., with the words, Mrs. A. Schuman, and an address at the end, conveying the notion of a signature, or at least that the words were hers. The plaintiff declared that she was not Mrs. Schuman, was not a nurse, and was a total abstainer from all liquors.

The court considers that the plaintiff had a case which it was her right to prove and have go to the jury. It was pointed out that there was no general consensus of opinion that to drink whisky is wrong, or that to be a nurse is discreditable. It might have been added that very possibly giving a certificate and the use of one's portrait in aid of an advertisement would be regarded with irony, or a stronger feeling, only by a few. But it appears to the court that such inquiries were beside the point. If the advertisement obviously would hurt the plaintiff in the estimation of an important and respectable part of the community, liability was not a question of a majority vote. There was some suggestion, to, that the defendant published the portrait by mistake, and without knowledge that it was the plaintiff's portrait, or was not what it purported to be. But that fact, if it was one, was no excuse. If the publication was libelous, the defendant took the risk.

Obviously an unprivileged falsehood need not entail universal hatred to constitute a cause of action. No falsehood is thought about or even known by all the world. No conduct is hated by all. That it will be known by a large number, and will lead an appreciable fraction of that number to regard the plaintiff with contempt, is enough to do the latter practical harm. Thus, if a physician were represented as advertising, the fact that it would affect his standing with others of his profession might make the representation actionable, although advertising is not reputed dishonest, and even seems to be regarded by many with pride. See Martin vs. The Picayune (Martin vs. Nicholson Pub. Co.), 115, La. 979.

Fees Allowed Family Physician

The Appellate Term of the Supreme Court of New York says that the plaintiff in the case of Haas vs. Read (117 N. Y. S. 106) sued to recover $300 for services as a physician rendered between October, 1907, and January, 1908. He resided next door to the defendant, whose wife and child he concededly attended until dismissed by the calling in of another physician. He sent in his bill for $300. The defendant retained it. Three months thereafter, the plaintiff insisting on its payment, the defendant refused on the ground that it was exorbitant.

On the trial the plaintiff testified to 57 visits, of the value of $5 each. The defendant conceded 42 visits, denied any others, and claimed the value of those made to be $2 or $3 each. He placed in evidence a bill rendered to him by the plaintiff for one visit, made in April, 1907, in attendance on Mrs. Read, for which he charged and was paid $4. The defendant's proofs as to the number of visits lacked probative force, while the plaintiff's was corroborated by written memoranda made at the time of each visit. The plaintiff called a specialist in children's diseases, with whom he consulted twice while attending the defendant's child, to prove the value of the plaintiff's services at $5 per visit; but the exceptions to that testimony were well taken, and it must therefore be disregarded. The defendant offered no evidence of other physicians as to said value, so that the plaintiff's testimony on that subject stood practically unchallenged. It may be assumed from the record that the plaintiff's attendance was as a family physician, not as a specialist in children's diseases. It would seem that by his previous charge of $4 he had established with the defendant his fee per visit.

The trial court found that 57 visits were made, at $5 each, and gave judgment for $285. This should be reduced to $228 ($4 a visit).

7 *Practical Test for I[illegible] Acid) in Urine. F. C. Askenstedt, [illegible]
8 Mental Hygiene. C. [illegible]

3. **Untreated Rabietic Virus.**—The practical value of using fresh *virus fixe* for the treatment depends on a single factor, and that is, that the *virus fixe* used must be absolutely atoxic and avirulent for the human being. In the last two years 40 patients have been treated under Proescher's direction. Some of these patients were bitten by dogs actually proved mad; others by dogs which were only suspected to be afflicted with rabies. No patients have died from hydrophobia and none showed any evidence of intoxication due to *virus fixe*. The first 10 patients were given two injections daily for ten days; 11, one injection daily for ten days, and the last 19 were given daily injections for six days. It is no longer necessary to dry the spinal cord, and at the same time the more virulent brain tissue can be used, thus eliminating the tedious and difficult dissection of the spinal cord. The using of fresh *virus fixe* is very advantageous to both physician and patient as it offers greater security than the old Pasteur method due to the giving of fresh *virus fixe* on the first day, thus losing no time in the immunization with avirulent *virus fixe*, which all authorities agree does not give any protection, but affords time for possible development of rabies. By the method described in this paper, the immunization time is said to be shortened two-thirds, and both trouble and expense are saved.

7. **Test for Indican.**—Askenstedt has evolved from the Obermeyer test a modification which, he says, though still possessing certain imperfections, yet combines the advantages of the ordinary quantitative tests for indican with a greatly simplified technic, rendering it the one best adapted to the requirements and limitations of the medical practitioner. The test is carried out as follows: To 10 c.c. of urine in a test tube add 10 c.c. of the ferric chlorid solution and mix by inverting the tube once; then add quickly 8 c.c. of chloroform, and extract the indigo in formation by shaking the tube 400 times, holding it in a horizontal position. After this let the chloroform fall to the bottom of the tube, then pour off most of the supernatant fluid, fill the tube nearly full with water, invert it a few times to wash the chloroform, and let this again precipitate in the tube, and pour off most of the water. Repeat twice this process of washing, taking care that no chloroform escapes with the wash water, and allowing not more than 2 or 3 c.c. of the last wash water to remain over the chloroform. Now add from 13 to 15 c.c. of alcohol and mix by shaking. A clear blue fluid should result. If hazy, add one or two c.c. more of alcohol until the fluid clears up. Compare the color of this fluid with an equal quantity of a standard solution of indigo blue in the second test tube by holding the two test tubes in front of a white surface. This standard solution is made by pouring into the empty second tube a quantity of water equal to the amount of the fluid in the first tube, and then dropping the stock solution of indigo blue into the water, inverting the tube after each drop, until both solutions have the same amount of blue color. If this requires four drops of the stock solution the percentage is 0.0004; if five drops, 0.0005; if six drops, 0.0006, etc.

The indican extract will often prove slightly greenish. By adding one or more drops of the picric acid solution to the standard solution in the test tube, this can be made to conform to the color of the extract. Albumin or bile in the urine will not interfere with the estimation; sugar reduces it. To compensate for indican not collected by the chloroform and the small amount lost in the washings, add 20 per cent. to the final result. Urine containing 0.002 per cent. or more of indican, or giving a blackish extract, should be diluted with equal quantity of water and retested.

20 Varicose Veins of the Leg. H. M. Chase, Boston.
21 *Arteriovenous Anastomosis for Senile Gangrene. J. C. Hubbard, Boston.

17. **Reticulated Red Blood Corpuscle.**—Hawes believes that the condition known as stippling of the red cells and that known as polychromatophilia are probably but different forms of the same process. Reticulated red cells, *"les hematics granuleuses,"* of Chauffard and Feissinger, as shown by simple vital stains, either in temporary or permanent specimens correspond to the stippled or polychromatic cell as seen in the fixed preparation, and are due to the same causes. Owing to the greater delicacy of the vital staining method, the reticulated forms will always be found in considerably greater percentages than stippled or polychromatophilic cells. All these phenomena Hawes regards as evidences of cell regeneration and indications of the activity of the blood-forming organs. Reticulated forms occur in normal blood in slightly less than 1 per cent.; in certain pathologic conditions they may be present up to 22 per cent., or even up to 65 per cent.

21. **Arteriovenous Anastomosis for Senile Gangrene.**—In Hubbard's case the circulation in the foot was sufficiently improved by the operation so that the color of the area, originally purple, changed and became almost normal in appearance, with the exception of the toes. Edema of the leg, which was slight at first, became excessive. It made the leg seem stiff and full to the patient. Coincident with the appearance of this edema, pain, which had decreased since the operation, returned, and from that time on became the most prominent symptom. Hubbard asks: Was this pain due to pressure exerted by the edema on nerves already in an enfeebled condition, or was it due to progress of the nerve changes started by the impending gangrene and not stopped by the apparent improvement in the circulation? He points out that the case demonstrated beyond dispute, for the first time in man, that an anastomosis can be performed which will remain patent for some time. The lesson taught by it is that a single anastomosis between the artery and the vein renders the return of the venous blood too difficult. A complete reversal of the circulation is, therefore, to be recommended. Whether this will prevent edema, and if so, the pain, remains to be seen.

31 Bleeding from the Intestinal Tract of an Infant in the Course of Alimentary Decomposition in the Sense of Finkelstein. S. Amberg, Baltimore.
32 Conveniences in Laboratory Technic. R. G. Perkins, Cleveland.

28. **Epidemic of Jaundice.**—Several features of this epidemic are emphasized by the authors. In the first place, the infectious character of the disease was clear. The sudden onset with chill, fever, headache, general muscular pains and leucocytosis are evidence of infection and intoxication. The negative results of blood cultures point to some local infection rather than to a bacteriemia. Secondly, the gastrointestinal features, nausea, vomiting, diarrhea and colicky abdominal pain make the diagnosis of gastroenteritis necessary, and this is in accord with the opinion that food, and probably meat, was the most likely source of the infectious agent. Thirdly, in every case the jaundice was obstructive in type, lasted only from two to three weeks, and exhibited the characteristics of catarrhal jaundice associated with gastroenteritis. A bacterial invasion of the bile passages and even the liver is possible. The finding of tyrosin in the urine of two cases is in favor of this. Fourthly, either water or food (the only things in common in these cases) must have been the source of the infection. The only positive results of the bacteriologic study in the authors' cases suggest the *B. paratyphosus* as the invading micro-organism. Two possibilities present themselves. Either it may be assumed that the bacillus already present in the intestinal tract of several prisoners rapidly multiplied during a period of lowered resistance from unknown cause, or the bacillus was introduced through the food. The sequence of events in these cases was as follows: (1) Ingestion of tainted meat, containing living paratyphoid bacilli; (2) development of a gastroenteritis due to this micro-organism; and (3) the appearance of a catarrhal jaundice due to extension of the gastroenteritis to the biliary passages.

33 *Milk-Sickness. E. O. Jordan and N. M. Harris, Chicago.
34 [illegible] Pathology of Milk-Sickness. A. B. [illegible]
35 *[illegible] of Anaphylaxis (II). H. G. Wells, [illegible]
36 **Coccidioidal Granuloma and Blastomycosis in the Central Nervous System.* N. Evans, Nashville, Tenn.
37 *Toxic and Antigenic Properties of Bacterium Welchii. E. F. McCampbell, Chicago.
38 Influence of Scurvy on Hemorrhages in Plague. W. B. Wherry, Oakland, Cal.

33. **Milk-Sickness.**—Jordan and Harris give a complete review of the literature as to prevalence in early and recent times, symptoms, theories as to nature and other features of milk-sickness, together with full report of the results obtained by them from the examination of recent cases of the disease in cattle and horses (New Mexico) and in human cases (Illinois). The most pronounced lesions found post-mortem in cattle are fatty degeneration of the liver and heart muscle; similar changes were found in the single human case examined after death. From practically all the cases of the disease observed by the authors in man and animals they isolated a characteristic aerobic, spore-bearing bacillus—*B. lactimorbi*—which they also found in the soil of so-called milk-sick regions. Injected into and fed to rabbits and guinea-pigs the bacillus has little or no effect. When fed to dogs and cats symptoms and lesions similar to those in animals naturally milk sick were produced. Jordan and Harris do not feel that their facts absolutely establish that this bacillus is the cause of milk-sickness, because, as shown by Luckhardt, the bacillus seems widely distributed, even in regions where the disease has never been known to exist, and from the feces of normal cows. It is possible that where soil or other conditions are especially favorable, strains of the bacillus may assume pathogenic or toxigenic powers.

Luckhardt's observations indicate that the bacillus may occur more commonly on certain plants than on others. In view of the rarity of material available for the study of this disease, the facts recorded will be of value to others who come across the malady from time to time.

35. **Chemistry of Anaphylaxis.**—The experiments indicate that proteins cannot be decomposed much, if any, beyond the coagulable form without losing their anaphylactic properties. In order to establish the reaction of anaphylaxis, intact protein molecules in soluble form are necessary. It seems that ovomucoid may have a specific anaphylactic action, reacting only with itself, a form of specificness not conclusively demonstrated in other biologic reactions. Ovomucoid remains active even after being heated several hours at or near the boiling point and after being precipitated with alcohol, so that it is evident that heat affects the anaphylactic properties of proteins only when it renders the proteins insoluble.

36. **Granuloma and Blastomycosis in Central Nervous System.**—The lesions in the central nervous system in a case of coccidioidal granuloma are reported. Microscopically, they resembled very much those of tuberculosis, but tubercle bacilli were not found, while typical encapsulated and sporulating fungi were present. The indications are that the nervous lesions in coccidioidal disease have a predilection for the pia mater, while the nervous lesions in systemic blastomycosis tend more to involve the deeper tissues.

37. **Properties of Bacterium Welchii.**—The toxic substances of *B. welchii* (*B. aerogenes capsulatus*) are not true bacterial toxins, but products of the bacterial cells capable of generating organic acids, and in infections these acids act as toxic agents. Butyric acid of the same acidity as the cultures of the bacillus produces the same effect. The hemolytic and leucocytotoxic action of the bacillus is also due to organic acids. Opsonin and bactericidal substances for *B. welchii* are present in normal rabbit serum and may be increased on immunization, which also gives rise to agglutinins and precipitins. In test-tube experiments only, little phagocytosis of the bacillus takes place unless the bacteria are first washed free from the organic acid, beause the acids neutralize the opsonins in the serum and also cause marked changes in the leucocytes. The proteins of *B. welchii* give the anaphylaxis reaction. As shown by Holst, guinea-pigs, when kept on a one-sided diet consisting of different sorts of grain, groats or bread, may die in eighteen days or so from a disease that corresponds macroscopically and microscopically to human scurvy. Wherry's experiments were made with guinea-pigs rendered scorbutic in this way, and he found more hemorrhagic extravasation in such scorbutic animals than usually is seen otherwise. Hence, plague and scurvy in the same person might lead to excessive hemorrhage.

41. **Anal Pruritus.**—Martin has modified the Ball operation in the following points: The use of a solution of cocain and adrenalin secures local anesthesia and a dry visible field for dissection. Radiating incisions do not endanger the nutrition of the parts. The corrugations of such flaps may be effaced by traction on their margins. A skin-tag may be removed within an elliptic incision, which by suture may be given a linear form. Radiating wounds require no suture, coaptate automatically when the patient is in extension and heal by first intention.

43. **Id.**—Hill advises instructing the patient to cleanse thoroughly the anal region after defecation, preferably with absorbent cotton soaked in some antiseptic solution, and then wrung dry. The parts should be protected from friction and the irritation of the discharge by wearing day and night an anal pad held in place by a T-bandage. The pad is best made with absorbent cotton wrapped with but one thickness of sterilized gauze. Too many thicknesses of gauze when ointments are used absorb the greasy portion of the ointment, and shortly the anal region becomes dry and coated, with only the irritating mineral ingredients left. The methods of applying and removing ointments are such important details that in the first few weeks of treatment the patient should be seen daily by the surgeon. To instruct the patient to use some of the ointment, morning and night, is not enough. Those cases in which the dermatitis is acute (eczema ani), accompanied by many excoriations from scratching and rubbing, require applications and ointments of a soothing and protective nature. In this latter class, in which the secretions are increased, Hill has found the *x*-ray of marked benefit. However, in the class of patients who are especially referred to here, the skin is nearly always tough and leathery and covered with dead and sodden epithelium. The problem in these cases is to bring about a gradual destruction of this newly formed epidermis, without too much inconvenience to the patient, and no agent, he asserts, serves the purpose better than nitrate of silver and citrin ointment applied as suggested by Adler.

It has been Hill's experience that in those cases in which the skin was considerably thickened and tough, the saturated solution of silver is more satisfactory. On the third day after its application, by placing hot fomentations over the anus for a few minutes, a layer of exfoliated epithelium may be removed almost *in toto*.

44. **Id.**—In order to derive the full benefit of Ball's original operation and still maintain the vitality of the flap, it is imperative that the flap dissected from the underlying tissue should receive its blood supply from the vessels coming from the skin; and that the circulation should be as abundant as possible. Krouse accomplishes this by making from 6 to 8 linear incisions through the skin and subcutaneous connective tissue. These linear incisions, beginning at a point outside of the point of irritation, follow the course of the radii of a circle whose center is the anal canal. The skin lying between the adjacent radii is then undercut until the whole affected area is undermined. Should the dissection be difficult, and more room be needed, then every alternate flap could be loosened at the anal margin and dissected outward toward the periphery. After all the adhesions are loosened and the bleeding has been stopped, the parts are again replaced and sutured.

47. **Vaginal Anus in the Adult.**—Hirschman suggests from his experience with two cases in the adult, that infants born with imperforate ani, in whom some abnormal outlet for the feces is present, it is far better to allow the patients to go on in their abnormal condition, until they grow old and strong enough for surgical interference and the correction of Nature's failure.

55. ***Ball's Operation for Internal Hemorrhoids.***—The results obtained by Combs with Ball's operation have not been so favorable as those that should follow the procedure, in the author's opinion. He found that the postoperative pain is greater than after the usual ligature or the clamp and cautery method. The duration of the healing period is not shortened because of the sloughing of the ligature from either the skin-ring or the pedicle before union takes place, leaving the wounds to heal by granulation. There is a necessity for unusual watchfulness that all ligatures may be removed as they slough. Failing to secure primary union, skin-tabs frequently remain for subsequent removal. No time is saved by this modification of the ligature operation. There is danger of secondary hemorrhage from an early tearing off of the pedicle by traction.

69. **Cyst of Wall of Carotid Artery.**—Freedman's patient died of acute lobar pneumonia. The autopsy which was performed three and a half hours after death, revealed the following pathologic conditions: acute left-sided lobar pneumonia, generalized arteriosclerosis, arteriosclerosis of coronaries and peripheral vessels, fatty change of the intima of the pulmonary artery, fatty and calcareous degeneration of the aorta, fibrosis of myocardium, calcification of papillary muscles, chronic interstitial nephritis and chronic mitral endocarditis. The generalized arteriosclerosis was of moderate grade, and affected not alone the aorta, but also the smaller vessels of the muscular type. In the right common carotid, at a distance of 2.5 cm. from its origin, and lying in a portion of the artery which showed few degenerative changes, was a small cyst with gelatinous contents occupying the middle zone of the arterial coat. The cyst was oval in shape, with its long axis running parallel to the direction of the vessel. The cyst lay on the anterior side of the artery, and from the inner surface of the vessel it was seen to project above the general level of the intima. Similarly when viewed from without, there was a definite bulging of the arterial coat in the adventitia. The intima covering the cyst was quite smooth and free from atheromatous or endarteritic change. Likewise, there was no evidencee of disease or of a neighboring inflammatory process on the external surface of the artery. The adventitia covering the cyst was quite pale and similar to the tissues in the neighborhood. On opening the cyst, it was found to contain a gelatinous semisolid substance, looking not unlike the colloid material of the thyroid. This material was of such consistency that it remained *in situ* after the cyst was bisected.

The inner and outer walls of the cystic cavity were formed by the arterial coats and were of about equal thickness. There was no evidence of a thinning of the vessel coats and the combined thickness of the inner and outer walls of the cyst was about equal to that of the wall of the carotid on either side of the cyst. Freedman claims this the only case of the kind on record.

79. **Bacterial Vaccines in Children's Diseases.**—Hoobler records the results obtained in the use of autogenous vaccines in 8 cases, each representing a general type of infection, in which he has used vaccines, but his conclusions are based on the outcome of all the cases on which he has used the vaccine treatment successfully. The paper reports the following cases: 1. Chronic bronchitis, following whooping-cough, complicated by acute purulent otitis media. 2. Bronchopneumonia, delayed resolution. 3. General rheumatic infection. 4. Septic infection after operation for double mastoid. 5. Streptococcic empyema following lobar pneumonia. 6. Streptococcic septicemia following acute purulent otitis media. 7. Furunculosis, complicating lobar pneumonia. 8. Furunculosis following infection from hypodermic injections. Hoobler claims for vaccines a place in the therapy of certain infective processes in children, which, until now, have resisted nearly all surgical or medical measures.

87. **Duration of Treatment of Syphilis.**—Hay says that the thorough and complete treatment of syphilis comprises methodical, intensive and prolonged administration of mercury, assisted with strict hygienic precaution, from the fifth to the twelfth year; complementary courses of treatment repeated every six or twelve months are necessary, and this treatment is not only curative but preventive. A properly treated patient usually escapes with slight secondary manifestations and his liability to later tertiary and parasyphilitic affections is notably diminished. In 95 patients thus treated the tertiary period remained mute and inoffensive. The offspring of these patients is practically immune in respect to heredosyphilis, and the women cease to be liable to repeated abortion.

95. **Sarcoma of the Upper Jaw.**—LaRoque mentions a dressing which he employs after the removal of the superior maxilla to substitute for the dental plate while this structure is being made, and thus allow the patient to take sufficient food and to speak distinctly. The dressing consists of an ordinary gauze strip about one inch wide and 12 inches long. About 6 inches of this strip are placed in hot paraffin so that the meshes will be impregnated by this substance. The paraffin is then allowed to cool and the other end of the strip is lightly packed into the wound while the paraffin end is moulded so as to form a sort of hard palate.

97. **Prevention of Nausea.**—Watson urges the patient to drink an abundance of water for two days preceding the operation, and receive saline enemas every few hours after the operation, to lessen the thirst, nausea and shock. When not contraindicated by the operation, he says that it is sometimes advisable when ether mucus has been swallowed to allow the patient to drink all the water desired as soon as consciousness returns; if this is vomited, the stomach is washed out, and if it is retained the ether mucus is diluted. Another method advocated by Kelly that is often successful in preventing nausea and vomiting following ether narcosis, is to wash out the stomach thoroughly at the conclusion of the operation and then leave in the stomach 6 ounces of a saturated solution of magnesium sulphate.

98. **Strangulated Hernia.**—When the gut is dark and suspicious Macrae makes an incision two inches long at the lower external border of the rectus muscle, draws the intestine out through this and wraps it in a towel or gauze wrung out of hot normal salt solution. The bowel is kept warm by repeated changes of gauze by an assistant while the operator proceeds with the operation for radical repair at the original site of the hernia. Much time is saved by this method by reason of the fact that no time is lost in the often tedious attempts made to determine the vitality of the gut. If after the operation for hernia is over, the gut is

found to have completely recovered, it may be returned and the second wound rapidly closed. On the other hand, if resection is demanded, it may be done more easily and thoroughly through the second opening, without interfering with the recovery of the original hernial site, which, if infected by the resection, is a most disagreeable complication. When the gut is absolutely gangrenous, with ulcerating areas, the intestine is drawn out until the normal healthy tissue presents, then tied off with strong silk, leaving the ends long. The dead portion is cut away, ends of the gut cauterized with carbolic acid and alcohol, hemorrhage controlled, and parts thoroughly cleansed. After a change of gloves, or rescrubbing, an incision is made, the same as described above, at the border of the rectus. The long ends of the silk are caught in forceps inserted through the second incision and the gut is drawn out through the latter. Macrae then proceeds to do a radical operation for hernia. In this class, however, he always provides two or more avenues for drainage. Attention is now directed to the bowel stump, general condition of the peritoneum, arterial pulsation of the mesentery, and other complications which may be present. When satisfied that the peritoneum is not sufficiently infected to cause trouble, the gut is united by any method most satisfactory to the individual surgeon.

105. *Abstracted in* The Journal, *Oct. 31, 1908, p. 1542.*

108. A similar article was published in *Surgery, Gynecology and Obstetrics*, February, 1909.

110. **Subcuticular Stitch.**—In using the stitch employed by Anspach any form of perineoplasty may be selected; the only modification required is to insert and bring out the perineal sutures just inside the peripheral limits of the denuded area. After the sutures are tied and the ends are cut short, the skin is united over them with a running subcuticular stitch. It is important to use well-prepared catgut, of medium size, which will not be absorbed in less than two weeks. The commercial chromic gut answers very well. Formalin-cumol gut is the ideal suture material. A finer size should be used for the subcuticular suture, but it must be 8 or 10 day gut. For this reason the ordinary cumol preparation will not do. The perineum is cleansed daily with sterile water. There is no need for the careful drying and powdering which external sutures usually require. The patient does not complain of the discomfort which tied or knotted sutures often occasion; there are no sutures to remove; the case is virtually out of the surgeon's hands when the operation is completed.

112. **Fracture of the Patella.**—LeMoyne emphasizes that satisfactory adjustment may be accomplished in the majority of cases by drilling the fragments in an oblique direction, so that the wire shall not enter the joint. In single fractures, one loop of wire will be sufficient in whatever direction the fracture line may be. In multiple fractures additional wires will be necessary. The unguarded points of the wires are liable to become engaged in the cavities of the cancellated structure which may be partially avoided by applying a small drop of solder to each point. Ample exposure of the fragments by suitable incisions and retractions of the soft tissues must be provided. Holes should be drilled for the wires, entering near the border of the internal surface of each fragment and passing in an oblique direction to terminate in the fracture surface, near the edge of the articular face; two being placed in each fragment of a single fracture, parallel to each other and about one-half an inch apart. The terminals of such holes in each fragment should correspond in their location as nearly as possible with those in the other. A loop should be made of annealed iron wire, with branches of equal length; the Malgaigne hooks with long curves, or some similar appliance, may be used to facilitate approximation during the tightening and twisting of the wire.

119. **Administration of Tuberculin to Wage-Earners.**—Ringer believes that it is in wage-earners that tuberculin has one of its most useful fields. Its administration, begun on the foundation laid by a strict regimen of hygiene and diet, finds the body at the outset in a receptive and comparatively well-prepared condition. Continued with moderation and with care, unhampered by the necessity for haste, aided and abetted by the constant physical supervision of the patient, finally sustained by short supplementary courses, it becomes the most potent medicinal agent in preserving the health and strength that have been restored by those three great surpassers of all specific medication: rest, fresh air and good food.

123. **Multiple Symmetrical Lipomata.**—Twelve years ago, the patient, a medical student, developed a skin eruption. This disappeared and reappeared at intervals for eight years, and was last seen four years ago. The patient recognized the disease as psoriasis. Shortly after the disappearance of the skin lesions, he noted numerous small masses under the skin. He complained of no discomfort or irritation from the presence of these tumors. The tumors had a tendency to disappear on massage, and some to reappear. Two on the abdomen disappeared permanently. The patient was a very well-developed muscular individual. There was considerable subcutaneous fat over the entire body. With the exception of the tumors the examination presented nothing abnormal or bearing on the pathologic condition. At the junction of the middle and lower thirds of each thigh in the anterior median line there was a subcutaneous tumor, ovalshaped, semisolid to the touch. The tumor was apparently fixed to the subcutaneous fascia, and was movable only with the skin. Each tumor was about 3x5 cm. in size; the long axis of the tumors lay in the long axis of the body. Two inches above, and two inches to the inner side of each tumor was a similar tumor at exactly symmetrical points in each thigh. These were slightly smaller and lie in the same axis. At the junction of the upper and middle thirds of each thigh on the anterior surface there was a similar tumor at symmetrical points. Each was about 2x4 cm. They lay in the long axis of the body. On the posterior surface of each thigh at the upper angle of each popliteal space there was a similar tumor, slightly smaller in size, same axis. One inch above each tumor in the popliteal spaces was a similar tumor, slightly smaller in size, same axis. On the posterior surfaces of the two thighs there were also six tumors arranged in three pairs at symmetrical points and lying in the same axis. One of the tumors was removed under cocain anesthesia for purpose of diagnosis. The tissue consisted of a lobulated mass 1x3x5 cm., and presented the typical gross and microscopic appearance of a lipoma.

134 Absence of Adrenalin in Malignant Renal Hypernephromas. J. R. Greer and H. G. Wells, Chicago.

128. **Cutting Branch of His Bundle.**—In all, 14 operations were performed by Barker and Hirschfelder, in 5 of which the left branch of the His bundle was cut without injury to the right. In all but one of the successful experiments this was followed by complete atrioventricular heart-block, but both ventricles contracted synchronously. The rhythm was the slow, regular, independent ventricle rhythm. In these experiments several cuts were made, and the heart stopped beating after a few minutes, so that it cannot be stated whether the complete block was due to the section of the branch and the trauma to the entire bundle, or was merely a terminal phenomenon. In one experiment, however, in which only a single cut was made, the ventricular rate remained entirely unchanged and no block was present. The heart continued to beat vigorously even after removal from the body. The left branch of the atrioventricular bundle was cut through, but the septum was not pierced and the right branch was absolutely intact. It would appear, therefore, that the His bundle plays little, if any rôle in the coordination of the two ventricles. The muscular bridge between the two chambers is formed by the entire musculature of the heart wall, and hence there is no such narrow connection as is present between atria and ventricles at which a block might be produced. It seems more probable that any such incoordination, if present, would be between the different layers of muscle fibers common to the walls of both ventricles, rather than between the two ventricles themselves, and that in some cases of apparent hemisystole seen in animals just before the heart stops beating (and after the circulation has ceased) the outer layer of fibers in one ventricle has stopped beating while the outer layer of the other (inner layer of the first) continues to beat for a few minutes longer.

129. **Experimental Parotitis.**—The principal, distinguishing or characteristic features of a diplococcus isolated by Herb from a case of mumps are the following: Gelatin is very slowly liquefied. In broth a slight cloudiness is produced in twenty-four hours; later a tenacious deposit forms in the bottom of the tubes. Milk is soured in twenty-four hours and coagulated in forty-eight hours. Potato produces a grayish-white abundant growth. Agar cultures show pearly white, tenacious, pin-point, round, discrete colonies. There is no production of indol. The organism occurs most frequently as a diplococcus, occasionally in small groups or chains of from four to six elements. It is non-pyogenic. When injected into Steno's duct in monkeys and dogs this diplococcus causes a diffuse non-suppurative parotitis, the infiltration being composed of mononuclear cells, and occasionally also orchitis of a similar character. In one case of human mumps (the only one studied) a similar rise of the opsonic index for this organism took place. Herb believes that there is consequently good reason to regard this diplococcus, which corresponds well with the description given by Laveran and Catrin of the diplococcus isolated by them from cases of mumps, as the actual cause of mumps and the disease produced in dogs as genuine experimental mumps.

130. **Hodgkin's Disease and Pseudoleukemia.**—In view of the doubtful etiology of Hodgkin's disease and the several synonyms which have been incorrectly applied, Symmers suggests the term "Hodgkin's granulomatous lymphoma" for the usual one of "Hodgkin's disease," because it designates the type of tissue in which the disease commences, the initial changes by which it is characterized, and the secondary changes that occur in the course of its development, while it reserves to Hodgkin the recognition that is due him. At all events, it is scarcely justifiable to employ the term "pseudoleukemia" as a synonym for "Hodgkin's disease," since the two processes, when fully developed, are readily separable and present totally different histologic alterations. From microscopic studies Symmers is convinced that there is a primary splenic form of Hodgkin's disease, and that the abdominal lymph nodes may be the seat of origin. The histogenesis of Hodgkin's disease, both in the lymphatic system proper and in the viscera, appears to be conceived in the formation of lymphomatous foci, while the characteristic granulomatous changes are sequential.

132. **Iodin in Thyroids.**—Marine and Lenhart summarize the results of their experiments as follows: 1. The tendency of all active hyperplasias is to revert spontaneously to colloid glands, and this change is hastened or delayed by the presence or absence of iodin. The amount of iodin given is of little consequence in normal and colloid glands, but is of the greatest significance in the active hyperplasias. 2. The ability of the glands to take up iodin does not depend so much on the form, mode or amount of its administration as it does on the degree of active thyroid hyperplasia. 3. There is a minimum amount of thyroid tissue below which iodin does not protect against compensatory hyperplasia. This limit is roughly the same whether colloid or normal gland.

133. **Gastric Fistula.**—Lavenson states that the importance of psychic stimuli in the production of gastric juice as determined by Pawlow and others in animals applies equally well to man. These psychic stimuli may be classified as positive and negative. Positive psychic stimuli are those which induce a flow of gastric juice. Negative psychic stimuli are those which inhibit or annul a gastric secretion. Psychic stimuli, both postitive and negative, may originate in the higher mental processes as memory and imagination, or, as is more usual, they may come from without and influence gastric secretion by appealing to any one of the five senses. Those stimuli which influence gastric secretion by appealing to the senses of taste or smell may be called direct psychic stimuli; those that act through the other senses or originate in higher mental processes may be called indirect or associated psychic stimuli. This dependence of gastric secretion on psychic processes and stimuli permits the formulation of the statement that appetite is the emotional expression of the group of phenomena of which the secretion of gastric juice is the psychic expression. The mechanical act of chewing seems to be powerless to induce a secretion of gastric juice; if the act of chewing becomes mentally associated with the process of eating agreeable food it probably is capable of inducing a flow of gastric juice. The human stomach appears to behave in the same way toward chemical stimuli as does the dog's stomach. Water is a definite though not a powerful stimulus to gastric secretion. Hydrochloric acid is not a stimulus to gastric secretion. Egg albumin does not induce the secretion of any more gastric juice than does an equal amount of water. The same is true of tea and commercial preparations of pepsin. Beef extracts are powerful stimuli to the secretion of gastric juice. Bitter stomachics, though of themselves incapable of inducing a secretion of gastric juice, when administered previous to a substance which does induce a secretion of gastric juice, are capable of increasing this secretion. In other words, they may be looked on as sensitizers of gastric secretion. This sensitizing action is manifested when the stomachic is introduced directly into the stomach or when it merely remains for a time in the mouth and pharynx. Its action seems to be more powerful in the latter case than in the former. From the observations Lavenson made on the effect of the introduction of acid and alkaline solutions into the stomach it appears probable that the predominating influence in the control of the periodic opening of the pylorus is exerted by the chemical reaction of the contents on the duodenal side of the pylorus. Though the chemical reaction prevailing on the gastric side of the pylorus is of importance in the pyloric mechanism, it is distinctly subordinate to that on the duodenal side. This hypothesis explains the slow discharge of gastric contents of high acidity and the more rapid discharge of gastric contents of low acidity.

2. **Cardiac Strain.**—With a view to coordinating ideas on the subject of cardiac enlargement in boys, Riviere carefully examined the hearts in a large number of boys taken at random, and also under conditions which necessarily throw a strain on this organ. The importance of the inquiry impressed itself on him as the result of an examination of a party of 40 boys chosen for a school holiday excursion, and a description of this excursion and its result form the basis of his paper. The party consisted of boys ranging from 7 to 14 years. The excursion was of a week's duration and planned to be of educational value; the locality chosen was a hilly district, the actual center being established on a hill at the height of 600 feet above sea level, with a climb of 400 feet from the valley below at the end of each day's tramp. Expeditions were undertaken daily, including the day of arrival and also that of departure. Breakfast was at 8 a. m. on most days, and an early morning walk at 6:30 a. m. was part of Sunday's program. The actual road distance covered each day was from 5 to 7 miles, but the expeditions lasted the whole of each day, the time being well filled with sightseeing and instruction. On two days the walking for the bigger boys was increased up to twelve miles. In addition to excursions any available time was given over to football and games. In short, it is obvious that the boys were subjected to considerable physical strain. At the same time the hours of sleep were decidedly insufficient; bedtime was 9 to 9:30 p. m. and lights were out at 9:45, but as the boys generally rose at 6 a. m. provision was made for but eight and a half hours of sleep.

The boys were medically examined ten days before starting, and were mostly well-built and sound. Examined again five days after their return, 20 out of 33, or rather over 60 per cent. of these healthy boys were found to show cardiac enlargement of various grades. This was, in most cases, no temporary condition, for at subsequent examinations at the end of two, four, six and ten weeks, only a few of the hearts each time had returned to normal, and 10 of them, or 50 per cent. still remained dilated two and a half months after the excursion. An interesting point was the age incidence of these cases of dilatation. Of boys of 13 and 14 years, only 3.6 per cent. suffered; at ages of 10, 11 and 12 years, 75 per cent. suffered, and among the youngest boys, of 7, 8 and 9, fully 83 per cent. were affected. With regard to the 7 boys whose hearts were already strained, in all but 1 there was an increase of dilatation in spite of restrictions.

3. **Administration of Oxygen.**—Moore claims that the usual methods of administering oxygen by delivering it from a steel bottle in a constant stream into a tube or funnel or open mask are so wrong in principle as to be practically useless,

and it is questionable whether the patient ever gets a mixture containing more than a small percentage of oxygen above the atmospheric amount, nearly all the oxygen escaping into the air of the room. The nature of the respiratory process is such that the patient does not require a continuous stream of oxygen bubbling out at or near the mouth, but rather a plentiful reservoir to breathe from rapidly each time he draws his breath. An apparatus based on this principle for continuous administration of a high percentage of oxygen consists of a collapsible holder, or gas-bag, sealed off from the air below by a water seal, and having in its base four large circular trays containing lime slaked with caustic soda for uptake of carbon dioxid during the breathing. The bag is first filled with oxygen, either made from the potassium permanganate, or obtained from a steel gas cylinder. The patient then simply breathes backward and forward into the bag through an air-tight mask and a very wide tube. There are no valves to obstruct the breathing, and the carbon dioxid is completely taken up by the soda lime. No discomfort whatever is felt in using the apparatus, nor was there any difficulty in breathing.

19. **Portals of Entry of Tubercle Bacilli.**—Cobbett endeavored to find out: 1. Whether or not bacteria can gain entrance to the lungs directly through the air passages. 2. Whether, after being absorbed from some part of the alimentary canal, they can pass at once through the lymph glands and gain entrance to the lungs. The general intention of the experiments was to throw light on the question of the portals of entry of the tubercle bacilli into the human body in the causation of phthisis. The experiments, as a whole, are not yet completed, but they show already that in the guinea-pig, bacilli suspended in the air readily pass down the bronchi deeply into the lungs. The experiments are not sufficiently advanced to justify conclusions as to the course of infection which follows the introduction of tubercle bacilli into the alimentary canal.

27. **Calomel in Asthma.**—Tivy prescribes a powder of calomel, from ½ to 2 grains, according to the habit of the patient, accompanied, of course, by some of the usual antispasmodic remedies, and his experience is that relief is rapidly obtained, even before purgation takes place. Other cathartic drugs do not seem to have the same effect or certainly not so rapidly, and the ease with which all the powder or tablet is taken is an important factor.

28. **Fractures of Mandible.**—Pickerill's method consists in fixing the lower to the upper jaw by means of horizontal ligatures passing round the crevices of two or more teeth in each jaw, the ligatures being securely connected by a *third* ligature. The method is said to be especially applicable to fractures at the angle of the mandible or in the region of the last molar tooth.

36 Juvenile Myxedema. D. A. Thomson.
37 Trypanosoma Dimorphon Dutton and Todd: T. Confusum, SP. Nova. R. E. Montgomery and A. Kinghorn.

33. **Arteriovenous Anastomosis for Gangrene.**—The patient, a very feeble old man, aged 69, complained of swelling, coldness, and feelings of pins and needles in his right leg and foot. The arteries were tortuous and thickened, the pulse tension was not high; the right leg and foot were cyanosed and the circulation in them was very sluggish. The pulse could be felt in the right femoral artery, but not in the popliteal or below it. Being fully aware that his leg was doomed if left alone, he was willing that an arteriovenous anastomosis should be done with the view of reversing the circulation of the limb and so attempting to stay the gangrene by conveying arterial blood through the branches of the veins. The operation was done under spinal analgesia. The upper end of the femoral artery was then sutured to the lower end of the femoral vein. Finally the internal saphenous vein was exposed at the upper end of the thigh and divided between ligatures, in order to close the most obvious of the possible short-circuits of the circulation of the limb. On the seventh day after the operation the condition of the leg was—no further extension of the gangrene, and a distinct pulse and thrill to be felt over the vessel as far as the adductor foramen. Fourteen days after the anastomosis it was necessary to amputate the leg by the circular method, a hand's breadth above the knee-joint. After dividing the main vessels it was seen that the vein (as originally constituted) was patent, while the artery was occluded with fibrinous clot. On tying the vessels and loosening the tourniquet the vein pulsated in the end of the wound exactly as a ligatured artery would. There was no blood extravasated in the sheath of the vessels, showing that the suture line had held absolutely fast.

35. **Congenital Dislocation of Hip-Joint.**—The operation done by Clarke consists in exposing the joint from behind, making a small opening in the lowest limit of the posterior aspect of the capsule, and introducing an elevator to raise the periosteum and with it the cotyloid ligament for a short distance at the upper and posterior borders of the acetabulum. Next three stout silk stitches are passed in turn through the periosteum, thus raised into the joint cavity under the cotyloid ligament, out of the capsule again and through a fold of the capsule, then once more through the capsule near its femoral attachment, where the two ends are tied. These stitches remove the over-distention of the back of the capsule and hold the cotyloid ligament over the outer part of the head of the femur. The limb is put up in plaster, as after the manipulative operation, which must always have preceded this open operation. The postoperative course is like that after the manipulative operation, and in the cases so treated there was no evidence of intraarticular adhesions being present when the plaster was removed. This proceeding differs from the open operations of both Hoffa and Lorenz, which involve an excavation of the acetabulum, and, when necessary, a reshaping of the femoral head through a free opening in the joint capsule.

43 *Painful Spots in Appendicitis. M. Lejars.

September 22

44 Diagnosis of [illegible] lacker.
45 *Disorders of [illegible] d Their Clinical Manifestations [illegible]

41. **Colostomy.**—Wallis again describes the operation he has performed for the past fourteen years with good results.

42. **Cerebral Circulation.**—In this lecture Russell discusses convulsions, physiologic mechanism underlying recovery from an epileptic fit, postepileptic phenomena, cerebral intravascular clotting as the cause of the epileptic fit, and vasomotor spasm in the brain as a cause of epilepsy.

43. **Painful Spots in Appendicitis.**—Speaking generally, says Lejars, the point of maximum tenderness, when clearly defined and fixed, affords a very fair indication of the situation of the appendix, but the area of tenderness spreads as the adhesions become more extensive. Certain is it that without carrying the search for the painful spot too far, thus incurring the risk of setting up hematomata of the mesoappendix, without departing from an attitude of caution and not neglecting lightness of touch, the direct and indirect exploration of the whole abdominal wall, and especially of the ileocecal region, from the point of view of pain, retains its importance in the diagnosis of appendicitis, with the reservation, however, that no exclusive importance be attributed to this or that spot in particular.

45. **Cerebral Circulation.**—Russel concludes his lectures by discussing migraine, *petit mal*, infantile convulsions, the symptoms following on sudden and prolonged cerebral anemia, and similar symptoms resulting from prolonged chloroform syncope.

48 *Gangrenous Inflammation of the Penis. E. Tédenat and J. Martin.
49 Backward Dislocation of the Forearm. (Luxation bilatérale et symétrique de l'extrémité inférieure du cubitus en arrière avec radius curvus.) R. Burnier and A. Neveux.
50 Fistula and Sequesters in Steno's Duct. (Fistule sténonienne.) Mauclaire.

47. **Sarcoma of the Stomach.**—Lofaro reports two cases from Durante's clinic at Rome and states that in 39 operative cases on record 17 of the patients did not survive the operation.

48. **Gangrenous Inflammation of the Penis.**—Tédenat has operated in two cases with superficial gangrene, and knows of a similar case on record, all with successful outcome. In four others the fascia was involved, one in his own experience, although there was more destruction of tissue in this group. In ten other cases the inflammation involved the corpus cavernosus, with total destruction, the list including two from his own experience. The general symptoms in this last group were severe, but only one of the patients succumbed. The only means of knowing the extent of the process is by early and deep incision, and this should be the rule, as otherwise a mild simple process may result in great destruction, as in a few of the cases reported. In one the abscess in the cavernosus was not discovered until at autopsy.

Obstétrique, Paris

August, II, N. S. No. 8, pp. 545-627

51 *Review of 148 Suprasymphyseal Cesarean Sections. (L'opération césarienne supra-symphysaire.) C. Jeannin.

51. **Suprasymphyseal Cesarean Section.**—By this term Jeannin means the Frank-Sellheim technic of operative delivery and he has been able to find records of 148 such operations which he here summarizes and compares from various standpoints. The method has passed through several phases since Frank proposed the suprasymphyseal transperitoneal Cesarean section in 1907. This was modified by Sellheim into an extraperitoneal technic, which seems to have the greatest vogue at present. The mortality of the mothers was 3.08 per cent. for the latter and 3.8 for the transperitoneal technic. The extraperitoneal method is more difficult on account of the danger of injury of the bladder. The total morbidity of the mothers with suprasymphyseal delivery was 30.7 per cent., including 25 per cent. from infection; the total mortality was 7.37 per cent.; from infection, 4.21 per cent., while that of the children was 8.18 per cent., or omitting the cases in which other causes were responsible, 3.62 per cent. Jeannin concludes his review with the remark that neither the figures nor the histories of the cases show that the suprasymphyseal technic has any advantage over ordinary Cesarean section, other things being equal, but if there is suspicion, but not actual certainty, as to infection, the suprasymphyseal technic is safer. Neither should be considered in case of known infection.

Presse Médicale, Paris

September 15, XVII, No. 74, pp. 649-656

52 *Sciatica of Tuberculous Origin. (Sciatique radiculaire d'origine tuberculeuse.) Lafforgue.

September 18, No. 75, pp. 657-664

53 *Transient Peripheral Neuritis in Parturients. (Des névrites périphériques transitoires dans l'état puerpéral.) E. Bonnaire and Rosenzwitt.
54 *Technic for Administration of Colchicum. (Comment il faut administrer le colchique.) A. Martinet.

52. **Sciatica of Tuberculous Origin.**—Lafforgue's patient was a young soldier, and the tuberculous nature of the sciatica was evidenced by exclusion, by the fever that accompanied each recurrence of the pain, the debility, tuberculous lesions in the right apex, positive seroreaction and the fact that there was no trace of endocarditis which apparently excluded rheumatism as the cause of the four serious and prolonged attacks of the sciatica. The sciatica was evidently of radicular origin, and due to toxins rather than to mechanical compression, as there were no signs of lesions in the spine or pelvis, and no lymphocytosis, while the comparatively rapid course of the sciatica and its complete subsidence speak also in favor of a toxic origin. There are about ten cases on record of typical radicular sciatica; syphilis or gonorrhea was incriminated in the etiology of the majority, but in two a tuberculous origin was beyond question. In the present case the subsidence of the sciatica seemed to have been hastened by potassium iodid, antipyrin and belladonna.

53. **Transient Peripheral Neuritis in Parturients.**—Bonnaire remarks that the slight transient neuritis generally fails to attract attention as the woman lies in bed, but that it should be sought for, as failure to differentiate it may lead to wrong therapeutic measures. Leopold Meyer found this transient neuritis in 1.7 per cent. of 1,000 parturients examined at Copenhagen, while in Bonnaire's experience at Paris it has been found in 4.7 per cent. The neuritis may involve one or more branches of a nerve; but the most usual site is in the lumbar plexus. Pain on pressure is the most constant and sometimes the only sign of the neuritis, but there may be also paresis of the psoas, anterior rectus or adductor muscles of the thigh. Spontaneous pain may be constant or intermittent and may range from slight to intense, exaggerated by movements. The pain follows the course of the nerve and may radiate to the front and inside of the thigh, with or without hyperesthesia or anesthesia of the skin above. The knee-jerk is exaggerated, and there may be slight edema and cyanosis of the leg. The neuritis may be bilateral but is generally confined to one side. This neuritis is frequently mistaken for phlebitis, and treatment is applied directly contrary to the indications for the neuritis. Instead of the immobilization required on suspicion of phlebitis, the limb with neuritis should be exercised and massaged to prevent trophic disturbances, atrophy and impotence. Mistaken treatment may thus transform an insignificant, promptly curable affection into a chronic infirmity. The pain of the neuritis can be differentiated from the disturbances resulting from the birth trauma by studying its localizations, not mistaking the sensitiveness of the body of the pubis, from relaxation of the symphysis, for a tender nerve. If a fold in the abdominal wall, just above the crest of the ilium, is taken up between the fingers, pain can be elicited by pinching the fold, in case of neuritis, while if the pain is deep in the abdomen it is merely due to soreness of the uterus and adnexa. The tenderness with neuritis is, of course, most marked at the point where the nerve emerges.

54. **How to Administer Colchicum.**—Martinet declares that when a patient is taking colchicum the slightest gastrointestinal disturbance, especially diarrhea, is an imperative warning to discontinue the drug. All the remedies for gout on the market, he says, contain more or less colchicum, and the gouty are liable to do themselves serious injury if they dose themselves without medical supervision. He has had 2 such cases of grave colchicum intoxication in his experience, and states that it is our duty to warn gouty patients of this danger.

62 *[illegible] Injection of Cocain. [illegible] Cocain in die Vene.) C. Ritter.

58. Abstracted in THE JOURNAL, Sept. 18, 1908, p. 968.

59. **Importance of Automatic Muscular Contractions in Spread of Gonorrheal Process.**—Schindler has studied the automatic muscular contractions in the genital organs which his experimental research has shown are a constant and physiologic phenomenon. These muscular contractions may also be elicited by reflex stimuli. They are an important factor in the spread of the gonorrheal infectious process, and treatment should aim to suppress them entirely. This can be accomplished by keeping the patients under the influence of atropin, and he makes it a rule to order suppositories twice a day, each containing 0.001 gm. atropin, or 0.002 or 0.003 gm. can be injected subcutaneously. The tolerance of human beings for atropin kept up for weeks is surprising. No massage of the prostate is allowed during the acute and subacute phase of the gonorrheal process, as this stimulates still more the muscular contractions which spread the infection. If the prostate is inflamed he adds 0.1 or 0.25 gm. potassium iodid to the suppositories. In connection with these measures to suppress the muscular activity he applies energetic local treatment to the urethra. He adds a few cases to show the details of and benefit from this technic. In this communication he refers especially to male patients, having reported last year the advantages of atropin in gonorrhea in women.

62. **General Anesthesia by Injection of Cocain Into a Vein.**—Ritter experimented on dogs and found that complete analgesia was induced by injection into a superficial vein of 10 c.c. of a 1 per cent. solution of cocain, or 5 c.c. of a 3 or 5 per cent. solution of the cocain in a 0.1 per cent. salt solution. The dogs lie quiet but alert, breathing normally, but insensible to the action even of the actual cautery applied to the penis, vagina, anus, tail, face, ear and lining of the mouth. There is no sign of pain and the dog wags his tail during these manipulations except when his tongue is seized with forceps. To this he objects, but not apparently because it is painful. The anesthesia lasts from fifteen to thirty minutes or more and none of the dogs showed any serious disturbances afterward. Only a few manifested any unpleasant by-effects, and these were all small dogs injected with unusually large doses. One dog reacted, however, always in the same way even to small doses. The disturbances noted were all of the same type; the animal becomes restless, tosses his head up and down in increasingly rapid tempo and, if placed on the floor, runs swiftly around in circles. This was kept up sometimes for fifteen minutes, after which the animal quieted down and was quiet and apparently normal by the end of the half hour or hour; actual convulsions were never observed with any dosage. None of the larger dogs showed any by-effects. The communication issues from Payr's clinic at Greifswald, but no clinical application of the method is reported, although the suggestion is made that this method might be applied possibly with "dammed circulation."

63 *Epidemic Cerebrospinal Meningitis at Zurich. (Beobachtungen bei den [illegible] Jahres 1908.) H. v. Wyss.
64 Pancreas [illegible] Importance of Changes in the Islands. Saltykow.

63. **Epidemic Meningitis in Zurich.**—Wyss relates the experiences at Zurich last year with 20 cases of epidemic cerebrospinal meningitis at the medical clinic. With one exception there was no known contact connection between the various cases which occurred in different quarters of the section, all between March and July. One case developed with a syndrome suggesting tuberculous meningitis and the patient was not taken to the hospital until after the third week, but no other case developed in the environment. The clinical picture varied with each individual. In one case a healthy young man was seized with stupor, stiff neck and furious delirium but no fever, and this condition persisted until death on the sixth day. In one case the stiffness of the neck and other symptoms ascribed at first to epidemic meningitis proved to be merely gonorrheal arthritis of the cervical vertebræ. The findings in the fundus of the eye were negative in all the cases, but lumbar puncture always confirmed the diagnosis suggested by the stiffness of the neck. If the spinal fluid is scanty and thick, the prognosis is grave beyond relief, as also when the fluid becomes exceptionally abundant as the disease subsides, showing that hydrocephalus is impending. The mortality in his cases was 50 per cent. and serious complications were observed in some of the others, such as total deafness in 2 cases, imbecility, decubitus and sepsis in 1, hydrocephalus in 2, phthisis bulbi in 1, and acute polyarthritis, or monarthritis in 1 and acute hemorrhagic nephritis in 2 cases, only one of the latter patients recovering. As the patients were seen so late in many instances his experience with serotherapy is not conclusive; it was applied in 15 cases with a mortality of 40 per cent.

71 Two Cases of Gonorrheal Serpiginous Ulcer in Men. Xylander.

65. **General Anesthesia.**—Recent research has shown that the anesthetics most soluble in fats and lipoids and less in water have the most powerful effect, and Verworn's experiments sustain the hypothesis that the drug enters into chemical combination with the oxygen-bearing group of atoms and thus renders them incapable of carrying oxygen. By this blockade of these groups of atoms the clinical facts observed are fully explained. During the anesthesia, the processes of oxidation are known to be paralyzed, while retrograde metabolism goes on as in asphyxia, that is, exclusion of oxygen, under other circumstances. The retrograde metabolism may even be accelerated during the anesthesia, and the tissues suffering from lack of oxygen may lose their vitality beyond redemption. There is no justification for identifying the condition of general anesthesia with that of sleep. During sleep the oxidations proceed and restitution results; during general anesthesia the taking up of oxygen ceases while the destruction of the living substance continues. It is thus seen that general anesthesia is not a stationary condition. The longer the anesthesia, the more the tissues suffer from lack of oxygen until asphyxia is complete. The loss of conductibility of a nerve in general anesthesia is due to the reduction in the intensity of the stimulus passing through the anesthetized area. This reduction occurs more rapidly the deeper the anesthesia. In applying "vein anesthesia," according to Bier's technic for local blockade of the nerve by intravenous injection of the anesthetic, the dose can be proportionately smaller, the longer the stretch of nerve exposed to its influence.

66. **Nervous and Mental Disturbances in Arteriosclerosis.**—Cramer emphasizes anew the great importance of early differentiation of arteriosclerosis of the central nervous system, as proper treatment may arrest the trouble and ward off social and material loss. When headache occurs and persists, with occasional vertigo, the possibility of arteriosclerosis should be suggested. The dizziness in these cases is extreme and unless the patient can catch some support he may fall. It is important to exclude vertigo from an ear affection and from varieties of true nervous vertigo. When due to arteriosclerosis, the memory for recent events is liable to suffer. The patients lose the thread of their discourse, forget the number of their room in the hotel, figures and names; they get into the habit of noting down whatever they wish to remember. A tendency to facile emotions and irritability may also be observed, and to lasciviousness. The local symptoms may indicate a neuron affection; among these he has frequently encountered a slowness in speech, first noticed by stenographers, or the speech may be difficult and indistinct. Sluggishness in the pupil reaction to light is another important differential sign, as also a difference in the innervation of the face. The reflexes are generally increased, and there may be pains and paresthesia. All these symptoms may occur on a purely nervous basis, and the arteriosclerosis can be differentiated only by exclusion and by remembering that signs of an organic affection of the

nervous system do not accompany a purely nervous trouble. It is much wiser to assume arteriosclerosis in case of doubt, rather than neurasthenia, as treatment of the larger includes the less. The mental disturbances of arteriosclerosis may be grouped as those showing decay of the mental power, depression, or conditions of exaltation with paranoia as the acme. It is characteristic for the latter group that the process occurs with remissions, leaving tranquil intervals simulating recovery. In progressive paralysis the entire personality seems to be changed more than in arteriosclerosis. The Wassermann reaction of the spinal fluid testifies to progressive paralysis.

70. **Gastric Ulcer.**—Payr's extensive experience has shown that the indications vary widely in individual cases, especially in view of the general health, the location, the anatomic form and the stage of the process. Gastroenterostomy is reliable, he states, for ulcers and resulting stenosis in or close to the pylorus. Tumors in the lesser curvature and rear wall of the stomach indicate transverse resection of the middle part of the stomach, which is much more promising than excision. Gastroenterostomy he considers a good palliative operation in these conditions when the general health does not permit a more complete operation. Jejunostomy under local anesthesia is advisable only in severe inanition. The slightest suspicion of cancer justifies resection, and a family history of cancer should turn the scale when gastroenterostomy is being considered. Very important is a course of internal treatment, as for acute ulcer, following the operation. This logical demand is frequently disregarded; the surgeon dismisses the patient on recovery from the operation, and sees him no more. Many patients with recurring ulcer are then encountered which throw discredit on operative treatment. Nowhere is the necessity for cooperation between internist and surgeon so important as in treatment and after-treatment of gastric ulcer.

80 Viscosimeter. (Die Viskosimetrie des Blutes.) W. Hess.

72. **Anatomic Changes in the Stomach with Tabetic Gastric Crises.**—Eichhorst remarks that it is by no means uncommon to have the tabes overlooked and the patient treated for the stomach disturbances alone, and reports a case of this kind in which a locksmith of 47 had been under the care of twelve different physicians during five years on account of attacks of pain in the stomach and vomiting. No relief had been obtained from the ulcer cures and other treatment instituted, and the emaciation suggested cancer. When the patient came into Eichhorst's hands, he examined for the knee-jerk but was unable to elicit it, which at once differentiated the unsuspected tabes, confirmed by other findings and the course of the case. The gastric crises of tabes may be either of a neuralgic, hypermotor or secretory nature or these combined, and in three of his patients there was tetanic contraction. As the contraction subsided the pain vanished. In two other cases he examined the stomach post-mortem; the patients were tabetic women, about 48, who had been under supervision for two and five years respectively. Notwithstanding the long duration of the gastric crises, the stomach wall was found free from even microscopic changes in one and in the other there were merely diffuse atrophy of the stomach glands and isolated proliferation of round cells—an interstitial insular gastritis. This case suggests that the tendency to emaciation in the course of tabes may be due to the increasing atrophy of the stomach glands.

74. **Testing the Reacting Power for Prognosis of Puerperal Fever.**—Sellheim has found it possible to foretell the course of puerperal fever by the response to a simple hydriatic measure. At the first visit he takes the pulse, temperature and respiration, and then has a broad tepid compress applied to cover the abdomen completely. Just as he leaves he notes again the pulse, temperature and respiration. If the temperature shows any signs of declining, the pulse growing stronger and slower, the blood-pressure rising and the respiration a tendency to become slower and less shallow under this simple hydrotherapeutic measure, he regards the prognosis as favorable. If the functions are not influenced in this way there is little hope of recovery, as the defensive reactions are at too low an ebb. The reaction on the part of the pulse and respiration to this mild stimulus denotes the degree of intoxication of the vasomotor system. This reaction test, in combination with the expression, the complexion, the tongue and pulse, reveal the outlook for the moment, and repetition every day permits constant control of the disease. At the same time the measure is an aid in treatment of puerperal fever.

91 *Syphilis Affecting the Muscles, Testes or Conjunctiva. (Zwei interessante Luesfälle und aus diesen Beobachtungen gezogene Schlüsse.) M. von Zeissl.

91. **Syphilis Affecting Muscles, Testes and Conjunctiva.**—One of the patients whose cases are reported presented severe myositis with orchitis, but electric tests of the muscles gave normal findings and under mercurial treatment all the disturbances vanished. In the other case the infection dated from a cut while being shaved; after various manifestations the syphilis entered a latent phase for a few months, but then severe conjunctivitis developed. It proved rebellious to mercurial and iodid general treatment, but promptly subsided when this was supplemented by local application of calomel. Previous local applications of other forms of mercury had not benefited; it is possible that the mercury accumulated in the organism first made itself felt at the moment of the application of the calomel. Zeissl has encountered in his practice forty-five cases of extragenital syphilis, including five in medical men, four of whom succumbed to cerebral manifestations, while the fifth recovered entirely after a period of right paralysis. In four other cases the primary manifestation was in the tonsils, and these cases were distinguished by violent headaches and exceptionally severe course.

Wiener klinische Wochenschrift, Vienna

92 *Aims and Tasks of Social Medicine. (Die Aufgaben und Ziele der sozialen Medizin.) L. Teleky.
93 Epidemic of Poliomyelitis in Vienna, 1908-9. R. Neurath.
94 Frequent Occurrence of Long Bacillus in Urine in Bacteriuria and Cystitis. (Das häufige Vorkommen des Boas-Opplerschen Bazillus im Harne bei Bakteriurien und Zystitisfallen.) A. Rodella.

92. **Social Medicine.**—Teleky refers in particular to the medical aspect of the compulsory insurance of wage-earners against sickness and accident, and emphasizes the new task which it has imposed on the profession. The physician not only has to treat the patient but he has to deliver a certificate and report on the ultimate prospects in the case. The surgeon also has had to change his aim; instead of trying to restore normal anatomic conditions he now endeavors to secure the best possible functional and wage-earning capacity. Social medicine is the borderland between medicine and applied sociology.

Its task is to enable each one to profit by the progress of individual hygiene and clinical medicine, to train physicians for these new duties, and to study the transformation in the status of the profession under the influence of these tendencies. He adds that the young student hungers for knowledge of real life on his emancipation from the parental roof, and in no other way can he obtain such an insight into real life than in studying, not only the sick, but the well, from this standpoint of social medicine, how people live, how they labor, and how they become diseased by their mode of life or their occupation.

95 *Dislocation of the Pelvis in Coasting Accidents. (Ueber schwere Beckenluxationen und Verletzungen der umgebenden Weichteile: Typische Rodelverletzungen.) A. Fischer.

95. Dislocation of the Pelvis in Coasting Accidents.—Fischer relates the details of an accident to a bob-sled on which six young men were coasting, seated in a row, the legs of each projecting beyond the fellow seated in front of him. As the sled ran into a tree, the impact of the pelvis of each against the sacrum of the man in front caused separation and dislocation of each of the articulations of the pelvis, with injury of the soft parts. The disturbances of this nature were the more severe the nearer the man to the front of the sled, except that the front man escaped this, but was killed by the concussion against the tree. Two others also succumbed to their injuries. Fischer obtained an unusual opportunity for autopsy of the different degrees of this typical coasting accident injury in these fatalities.

98 Modification of Hysterectomy Technic. (Zu dem Vorschlage Zweifel's "Ein neues Verfahren zur Exstirpation des Uteruskarzinoms.") C. Lauenstein.
99 *Plastic Operations on Abdomen. (Bauchdeckenplastik.) Weinhold.

97. Treatment of Eclampsia.—Uthmöller reports success in the treatment of severe eclampsia in two cases by evacuating the toxins by extensive venesection. This not only helps to eliminate the toxins but relieves the pressure on the circulation and, last but not least, weakens the body until it is unable to react to the eclampsia toxins with the convulsions. He withdrew 1,250 c.c. of blood in one case and about 900 c.c. in the other, applying no other treatment.

99. Plastic Operations on the Abdominal Wall.—Weinhold declares that too little attention is paid to improving the appearance of the abdomen when a laparotomy is necessary for any cause. It is not enough to restore previous conditions; the shape of the abdomen should be improved if needed. He describes several cases to show the advantages of doing this. In one case he removed 11½ pounds of skin and fat restoring the large pendulous abdomen to normal outlines. After a plastic operation of this kind he orders a stout bandage worn for a year, after which it is no longer necessary. Six illustrations of the technic followed accompany the article.

105 *Serotherapy of Erysipelas. (Ricerche sperimentali e considerazioni intorno al probabile meccanismo d'azione del siero Behring nella cura dell'eresipela.) G. Migliacci.

103. Epilepsy with Apoplectiform Symptoms Benefited by Organotherapy.—Trevisanello reports a case interesting from the prolonged and varied syndrome presented by the patient, a man of 31, who was under observation for a number of years, and from the apparently complete cure under treatment with nerve and brain extract, the cure persisting two years to date. The symptoms indicated a combination of hysteroneurasthenia, cerebral endoarteritis, epilepsy with apoplectiform manifestations, cerebral hemorrhage and consecutive hemiplegia.

104. Serous Meningitis.—Rossi reports 3 cases in patients of 20 and 28, including two men, one of whom succumbed to the disease. This patient was taken to the hospital practically moribund, the symptoms suggesting tuberculous meningitis. But the sudden onset of the symptoms less than a month before, with fever, excluded the tuberculous form, and lumbar puncture gave a limpid sterile fluid under high pressure. Blindness came on early, the early development of choked disc being another element in the clinical picture which testified to almost immediate diffuse and uniform increase in the endocranial tension, such as is observed otherwise only with acute hydrocephalus. In the woman, the first symptoms of the serous meningitis appeared in the third week of typhoid, but subsided in six days. In all the cases there was a basis of inflammation for the effusion, the condition blending into that of "meningism" without distinct demarcation. The fluid is always serous in this form, although possibly containing slight amounts of fibrin.

105. Diphtheria Antitoxin in Erysipelas.—Migliacci analyzes the various reports that have been published on this subject and describes his own experimental and laboratory research to explain the benefit observed from the antitoxin in the clinic. He found that the antitoxin induced pronounced leucocytosis in the animals, involving chiefly the polynuclears. The findings indicate that phagocytosis is a secondary phenomenon due to the presence of certain substances in the blood serum, the opsonins, which he believes to be a secretion of the leucocytes, not a product of their disintegration. Injection of diphtheria antitoxin seems to favor the production of these substances and thus to promote phagocytosis—its action reenforced by its power to induce leucocytosis. The benefit from the antitoxin was marked in his three clinical cases, as also in a number that have been reported by Italian writers in addition to Babes, Cantu and some Russian writers.

112 Behavior of Nitrogen and Iron in Two Cases of Ankylostomiasis. (Sul comportamento del gruppo azotato e del ferro in due casi di anchilostomiasi.) P. Petrarca.

107. Transplantation of Vasa Deferentia into Urethra.—Boari gives an illustrated description of an operation which supplies an outlet for the spermatic fluid after perineal prostatectomy in tuberculous affections of the prostate and bladder, and in traumatic injury of the vasa or organic impotency from atresia of the ejaculatory ducts. His experiments on large dogs confirmed the practicability of the operation, which he then performed with success on a man of 60 requiring perineal prostatectomy for hypertrophied prostate. The vasa are severed through an incision 4 or 5 cm. long on the scrotal raphe, as high up as possible, and the peripheral stumps are sutured together, bringing them together like the barrels of a gun. Thus sutured, they are brought into the anterior urethra through a transverse incision and fastened in place.

108. Iced Liver of Traumatic Origin.—In the case reported by Gazzotti, a man of 51 had been kicked in the right iliac fossa by a horse. The injury was followed by high fever and daily chills for two weeks. After this he felt better, but suffered from intense thirst, irregular bowel functioning and abdominal pain, which commenced in the linea alba but spread throughout the abdomen, which became enlarged. The amount of urine decreased and edema and ascites developed. The patient soon succumbed to the progress of the diffuse traumatic peritonitis. He had been previously healthy except for smallpox and malaria before the age of 20 and influenza at 28. Autopsy revealed a typical iced liver only half the normal size, and the various steps of the process could be readily traced.

109. Changes in the Spleen with Cirrhosis of the Liver.—Egidi concludes from research on this subject that the changes observed in the spleen with cirrhosis of the liver should not be confounded with the changes and enlargement of the spleen from chronic congestion. It seems to be evident that the cause inducing the lesions in the liver acts on the spleen in much the same way. It is absurd to assume that the entire syndrome of cirrhosis of the liver is due exclusively to this organ, or to mechanical congestion in other organs. Changes are found in other organs which are beyond the influence of congestion from this cause, such as the transformation of the yellow bone marrow into red marrow, which has been cited as an argument in favor of the assumption that cirrhosis of the liver is primarily an affection of the blood. In conclusion he tabulates the details of the twenty cases on which his communication is based.

117. Reactivation of Saliva as Test of Pancreas Functioning.—Romanelli has applied for this purpose the discovery of Roger and Simon that saliva, inhibited in its special activity by the gastric juice, recovered its specific properties when transferred to an alkaline medium and a little unmodified saliva or pancreatic juice added. The findings with this test applied to the feces were always confirmed by the ordinary reliable tests of pancreas functioning. The test is not only qualitative, but also gives a quantitative estimate of the proportion of pancreatic juice present. The test is made with 1 c.c. of the individual's saliva mixed with 5 c.c. of gastric juice or an equal amount of a 2.5 per cent. solution of hydrochloric acid. After thorough mixing and an interval of rest of about half an hour, he adds 4 c.c. of a 1 per cent. solution of sodium carbonate to render the mixture slightly alkaline, and then he adds 20 c.c. of a 10 per cent. starch paste. The whole is then kept in the incubator for two hours, at a temperature of 37 C., shaking up the mixture at intervals. It is then examined for the proportion of sugar that has been produced, and then 10 c.c. of an emulsion of fresh feces (1 part stool to 3 parts distilled water) are added to the mixture, which is then replaced in the incubator, shaking it up occasionally. After twelve hours the qualitative and quantitative determination of the sugar that has been produced testifies to the intensity of the pancreatic functioning. The variation in the findings in regard to starch digestion in the first and second examinations give an oversight of the conditions in respect to the saliva and pancreas functioning when compared with the findings in health.

Ugeskrift for Læger, Copenhagen

September 9, LXXI, No. 36, pp. 999-1020

of Trigeminal Neuralgia. T. Levison.

119. Treatment of Trigeminal Neuralgia.—Levison discusses the various methods of treating the malignant form of trigeminal neuralgia, which is rebellious to the salicylates. The pain does not radiate as in the mild form, and there is no local tenderness. It is liable to be brought on by movement of the face muscles, laughing, sneezing, etc., and in order to avoid this the patient is inclined to hold his features still, which imparts a characteristic expression. Levison ranks aconite highest after the salicylates in drug treatment and has had good results in some patients with this type of neuralgia; they took from one to four pills of aconite three times a day. In four the neuralgia was over ten and in the others from one to three years' standing. In three cases the effect of the aconite was marked; another patient was benefited more by potassium iodid. Levison refers in particular to Vitek's method of treating the neuralgia with a weak electric current, with one anode in the mouth to act on the second and third branches, the other under the upper eyelid to act on the first. In some of Levison's patients the neuralgia had returned after Gasserectomy. Deep injections of alcohol offer the best prospects in treatment of neuralgia rebellious to drugs and physical measures, he is convinced.

THE PRESENT STATUS OF THE SERUM THERAPY OF EPIDEMIC CEREBROSPINAL MENINGITIS *

SIMON FLEXNER, M.D.
NEW YORK

My intention is to present a very brief statement of the status of the serum treatment of epidemic meningitis. It is now about three years since the serum was first used therapeutically in this country. Gradually its employment has extended until now it is being used in Great Britain, France and Germany, as well as in the United States and Canada. Indeed, the Rockefeller Institute has sent supplies to India and to Jerusalem, but, as no reports have been received from these distant places, they will not be further considered at present.

At the time of the first employment of the serum in this country the epidemic of meningitis had already receded in the East, and, although the disease spread westward even beyond the Rocky Mountains and was often very severe and fatal, yet the number of cases arising or being recognized in any one community was not large. I, therefore, view the test made of the serum in America as having coincided with the period of recession of the epidemic.

At the period of the first employment of our serum in Belfast and Edinburgh the epidemic was at its height; that is to say, it had reached its maximum development, from which it was tending to recede rather than to extend. All the evidence at hand shows that the disease at that time had not diminished in virulence and fatality, but the number of cases appearing was in a given time less than before.

In Germany, also, the epidemic was virtually at an end when the serum was received. In France, on the other hand, the serum was available at the beginning of the outbreak of the epidemic which is now prevailing in Paris and the provinces. To the fortunate circumstance that Professor Calmette, on his return from the International Congress on Tuberculosis, carried with him to Lille a considerable quantity of the serum is to be ascribed its prompt employment. Subsequently the Rockefeller Institute sent large supplies to him, to Professor Netter and to Professor Roux. The reports of the serum treatment now appearing in French medical journals are based chiefly on the employment of the serum prepared at the Rockefeller Institute.

If, therefore, the decision of the value of the serum treatment was properly withheld until the opportunity arose to subject it to a test at the beginning of a severe epidemic, when the fatality is commonly at its height, this opportunity has now arrived in France. The outlook is further promising for a comparative study of cases of epidemic meningitis treated with the serum and in other ways. While the serum is being employed widely, apparently, in Paris and in the intense way that experience has indicated to be the best, namely, by successive injections of relatively large doses, in the provinces it is being less generally employed and it has been found difficult to have the intense method carried out by the provincial practitioners. When the reports are all in and the figures have been collected we may expect, therefore, valuable information on the value of the serum.

In the meantime, I can report to you that the excellent results obtained from the serum in America and Great Britain are being repeated in France. There have already been published reports covering 100 or more cases of the disease treated with the serum in which the mortality will probably be less than 25 per cent. On the other hand, a smaller number of cases thus far reported treated by other methods have given a far greater mortality and one approaching 80 per cent. Moreover, the phenomena of diminution in severity of the symptoms and reduction of the period of infection and convalescence have been observed there as elsewhere.

We may, then, consider fairly, I think, that the serum treatment has now been subjected to test under a variety of conditions, some of which were as severe as probably ever occur. And yet I should still advise caution in concluding that the case has been proved for the serum. The total number of reports of cases of epidemic meningitis treated with the serum prepared at the Rockefeller Institute which I have collected is under one thousand, and it obviously will take a larger number than that to establish its value. I wish now to present a tabulation which has recently been prepared based on 712 cases of the disease in which the bacteriologic diagnosis was made and the serum treatment used. In the first table the cases are subdivided according to certain age periods, and in the second the total cases of each age period are further subdivided according as the serum was injected in the three arbitrarily chosen periods of duration of the disease.

TABLE 1.—CASES OF EPIDEMIC CEREBROSPINAL MENINGITIS TREATED WITH THE ANTIMENINGITIS SERUM

CASES ANALYZED ACCORDING TO AGE GROUPS

Age years.	Total no. cases.	Recovered.	Died.	% Mortality.
1-2	104	60	44	42.3
2-5	112	82	30	26.7
5-10	113	95	18	15.9
10-15	101	73	28	27.7
15-20	107	72	35	32.7
20+	175	106	69	39.4
Total, all ages	712	488	224	31.4

Table 1 brings out several points of interest. The highest mortality is shown to have occurred in the first

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

two years of life. But contrary to the rule under the older forms of treatment in which the mortality was 90 per cent., or over, in this series it was 42.3 per cent. The second age period is from 2 to 5 years, in which the mortality was 26.7 per cent. The third age period embraces children from 5 to 10 years of age and gave the lowest mortality of all, namely, 15.9 per cent. The next period extends from 10 to 15 years and gave a mortality of 27.7 per cent. The next period of from 15 to 20 years showed a considerable rise in mortality, equaling 32.7 per cent., and the last period, embracing the cases of 20 years and over, gave a mortality of 39.4 per cent. The average mortality in all the age periods was 31.4 per cent.

The time allowed me is insufficient to enable me to enter into a detailed discussion of the figures. It is my intention, however, to consider them in some detail in the near future. A point of importance and one to which Dr. Jobling and I have already referred is the importance of experience with the serum in securing the best results from it. If the separate large series of cases treated by individual observers are analyzed, the great discrepancy in the results as between children over 2 years of age, young adults and adults past 20 years are not encountered.

TABLE 2.—CASES OF EPIDEMIC CEREBROSPINAL MENINGITIS TREATED WITH THE ANTIMENINGITIS SERUM

CASES ANALYZED ACCORDING TO DAY OF INJECTION

	Period of Injection—Day.								
	1st-3rd			4th-7th			Later than 7th		
Ages. Yrs.	Rec.	Died.	%	Rec.	Died.	%	Rec.	Died.	%
1-2	16	1	5.8	22	10	31.2	22	33	60.
2-5	24	6	20.	40	12	23.	18	12	40.
5-10	43	8	15.6	35	6	14.6	17	4	19.
10-15	36	8	19.	23	9	28.1	14	11	40.
15-20	25	17	40.4	25	8	24.2	22	10	31.2
20+	36	21	36.8	34	24	41.3	36	24	40.
Totals..	180	61	25.3	179	69	27.8	129	94	42.1

Table 2 is instructive in bringing out the importance of early injections of the serum. The results in the first two years of life are especially noteworthy. The extraordinary figures given under the first period of injection, namely, in the first three days of the disease, can hardly be maintained. But the influence of period of injection is shown by the rapid rise in mortality in the subsequent two periods. The rule of the effects of early injection is preserved in the age periods up to the period of from 15 to 20 years, when it disappears. The discrepancy occurring in the two highest age periods cannot be wholly accounted for at present. The explanations which suggest themselves are that among older individuals there tends to be a large number of very severe, rapidly fatal or fulminating cases of the disease, or that older persons are less subject to the beneficial action of the serum. As regards the actual proposition, it may be stated that adults not infrequently respond promptly to the serum injections by abrupt termination of the disease or ameliorated symptoms and pathologic conditions.

The total figures do not, however, fail to indicate that the early injections are more effective than the later ones, as is shown by the percentage mortality in the first-to-third-day period of 25.3, in the fourth-to-seventh-day period of 27.8, and the period later than the seventh day of 42.1.

There is one consideration which I should like to touch on. The study of certain groups of cases of epidemic meningitis, coming under one observer, indicates that the diagnosis can sometimes be made before the usual symptoms of meningeal irritation appear or are recognizable. The cerebrospinal fluid removed by exploratory lumbar puncture has been, in these cases, sometimes clear and sometimes turbid and contained more or less polynuclear leucocytes and always *Diplococcus intracellularis*. The serum being injected immediately, these cases almost invariably were abruptly terminated or ran relatively a mild course. Attention having been drawn to the cases as being possibly examples of epidemic meningitis because of the similarity of the prodromal symptoms to those of other cases diagnosed later after the signs of meningeal irritation were plain, they ran a short and mild course after the early administration of the serum, while the others, which served to direct the attention, having been injected later when the infection and inflammation were well established, assumed a far more severe and protracted form.

Rockefeller Institute for Medical Research.

ABSTRACT OF DISCUSSION

Dr. Thomas Morgan Rotch, Boston: In my wards at the Children's Hospital during the last ten years, I have had on an average twenty of these cases each year. The children treated were in the first twelve years of life and I have carried out a different form of treatment during each of the past six years. During 1899, 1900, 1901 and 1902 no special treatment was employed and the mortality varied from 60 to 80 per cent. During 1903, 1904 and 1905 the treatment was by repeated lumbar punctures and the mortality continued from 60 to over 70 per cent. Although the lumbar punctures produced no notable change in the percentage of deaths yet a certain temporary amelioration was noticed at times. During 1906, all the children were treated with diphtheria antitoxin, the doses varying from 115,000 to 144,000 units according to the age of the child. An analysis of these cases showed no especially favorable results, the mortality being about 80 per cent. During 1907, in connection with my work on the opsonic index the treatment was with the vaccines and the mortality still remained up to about 80 per cent. In all the nine years from 1899 to 1907 the mortality varied from 60 to 80 per cent.

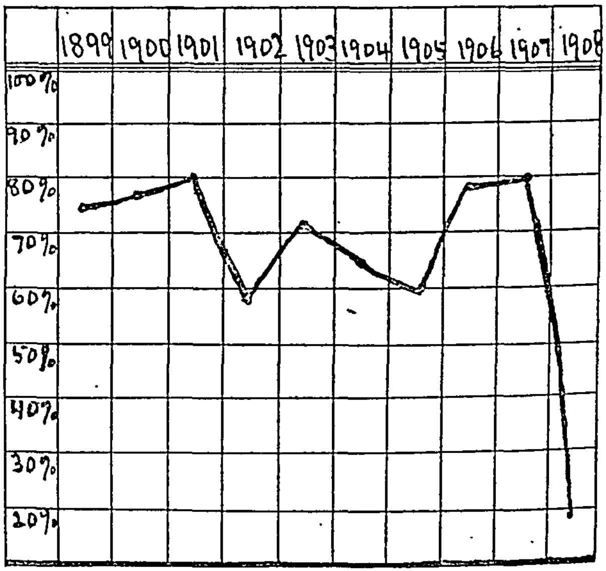

Chart showing death rate from epidemic cerebrospinal meningitis at the Children's Hospital, Boston, from 1899 to 1908.

From Nov. 1, 1907, to Nov. 1, 1908, the Flexner serum was employed and the mortality immediately fell from 80 to 19 per cent. This lower rate of mortality has varied a little since Nov. 1, 1908, but has never gone above 25 per cent.

The technic of the serum treatment in these 74 cases has been carried out by Dr. Charles Hunter Dunn. The amount of serum given varied according to the case but from 30 to 45 c.c. at a dose was found to be safe, given daily for at least four days. It is seldom that too much serum is given. In one patient, a small baby, symptoms of cyanosis, irregular respiration and collapse occurred but the symptoms soon passed off and in the Dunn series only one other child was affected and this not seriously.

The mistake which is most likely to be made is the giving of too little rather than too much. It is also a mistake to stop repeating the dose until grave symptoms return. The serum should be repeated at least once a day and in grave cases oftener until not only all symptoms have disappeared, but until the organisms are no longer found in the spinal fluid. Reports as to the results do not give a fair idea of the value of the serum treatment unless the technic is carried out in the most perfected way. In this series of 74 cases the technic was carried out with the greatest precision with the method approved by Flexner.

The serum treatment should not be mistrusted or given up because certain patients do not respond to it. There are two reasons why some individuals do not respond to the serum: 1. Because in some cases it is probable that the serum can not reach certain parts of the brain infected. For instance, if by the inflammatory process brought about by the disease the foramen of Magendie has been closed the organisms may still be active while enclosed in the ventricles where the serum can not reach them or in like manner perhaps in some remote cerebral sulcus. 2. It has not been proved that there are not a number of strains of *Diplococcus intracellularis,* some of which may be resistant to the serum.

In those cases in which an individual does not respond to the serum, cultures from the spinal fluid should at once be sent to the Rockefeller Institute in order that Dr. Flexner should be enabled to investigate this possibility and perhaps later be able to increase the polyvalent property of the serum by including them in immunizing his horses. Analogous to these characteristics of the *Diplococcus intracellularis* is the well-known efficiency of certain strains of the lactic acid bacillus and the uselessness of others on certain fermental saprophytes in the intestine. The truth of these observations has been exemplified in Dunn's clinical work.

Dr. Philip King Brown, San Francisco: Dr. Rotch's statement regarding the care of these patients in hospitals makes me wish to report a brief experience with the treatment of these cases in country towns in California where the disease seems to be endemic. It appears in epidemic form occasionally in small isolated communities. I wish especially to speak of this because of the remarkable results obtained in the use of the serum by the country practitioners and they should be given the credit of the work. I can not allow this opportunity to pass without speaking of it because of its bearing on the general use of the serum which I believe is bound to come. In all but one group of cases the serum was administered by the physician to whom I gave it, after I had made the initial injection. The most striking results occurred in one small town where eleven patients died before the serum was used. Then in a twelfth doubtful case the child recovered. The deaths occurred in periods of from five hours to four days after the onset of the initial symptoms. After the introduction of the serum, three patients promptly recovered. The fourth case died because the supply of serum gave out. A fifth patient from a distant place, ill two weeks before the serum was tried, recovered after the use of a number of doses of the serum. In a number of localities where I have gone to administer the first dose of the serum, I left a supply to be used by the local physician in the further care of patients and in subsequent cases that might arise. The best results obtained in California were obtained by the country doctors. In one late case the patient was deaf and nearly blind when the serum was begun; the sight returned to normal, but the hearing was not recovered. In another case the patient was almost blind before the use of the serum, but the sight was subsequently regained. Strange to say, the results in San Francisco were not so good as in the country towns. I did the work myself and did the best I knew how, but still I was not able to obtain the results obtained by the men in the country. Generally speaking, this seems to have been due to the late use of the serum, to complications and to the very bad hygienic surroundings in the homes of several of the patients. In no case, however, did I have to contend with the difficulties and disadvantages hygienically and as regards assistance in carrying out the treatment that attended all the cases I saw in the country towns and still my results were not as good as the country physicians'.

Dr. William Litterer, *Nashville, Tenn.*: There has just been an epidemic of cerebrospinal meningitis in Nashville. The number of cases was 20, which was confirmed by bacteriologic examinations. Dr. Flexner kindly furnished us all the serum that we needed. In the first three cases in which the serum was not used, the patients died promptly. Out of the seventeen remaining patients in whom the serum was used, only 7 died; 3 of those who died were practically moribund when the serum was injected. The serum acted like magic on 2 moribund patients. Leaving out the moribund patients, 4 out of the 14 died.

We were particularly struck with two cases in which the *meningococci* were found in fairly large numbers in the fluid. After the first injection of the serum the number had decreased materially and by the third injection cultures were absolutely negative and the spinal fluid perfectly clear, yet the patients complained of agonizing headaches which were the chief feature of these cases. One of the patients died on the eighth and the other on the sixth day of the disease. I am of the opinion that the meningococci had extended into the ventricles of the brain and that the serum could not reach them. I am further of the belief that possibly we could have saved the patients had we injected the serum into the ventricles of the brain.

Dr. Simon Flexner, *New York*: There are two symptoms which are likely to persist after the disease has entirely yielded to the treatment, namely, rigidity of the neck and the Kernig sign. Other things being favorable, they can be disregarded, and may persist even for several weeks, and gradually disappear. A second point I should like to refer to is that apparently certain strains of the diplococcus are more resistant to the destructive and inhibiting influence of the serum already mentioned. How to explain this I do not know. I had intended to collect some of these strains for a special study, but have had little success in securing them thus far. The cases have occurred often in distant and widely separated places, so that the cultures of the resistant diplococci have not survived the journey by mail to New York, and so far I have not succeeded in securing such resistant strains in New York. I trust to pursue this investigation in the future.

I am confident that the inflammatory exudate is sometimes formed in inaccessible parts of the meninges, or in deeper parts of the brain where the serum can not reach. Then in cases of hydrocephalus the obstruction at the base of the brain often prevents the serum from reaching the cerebral meninges and ventricles, where the exudate is contained. Cushing of Baltimore first carried out intraventricular injection of the serum in children in whom this obstruction existed, after trephining the skull; and in young children it is possible to make the injection through the anterior fontanelle, but up to the present time in no case of this kind, so far as I know, has the patient recovered. Whether better results will be obtained later can not of course be predicted, but in any event I think the operation justifiable, since these cases always terminate fatally.

Finally, I wish to express my deep sense of indebtedness to the large number of physicians, many of whom I have never met, for their hearty cooperation, which I appreciate very much, and without which this wide investigation could not have been made.

Fly Poison.—Formalin, used as a poison for flies, needs to be swallowed by the insect, hence the flies must be attracted to the poison by mixing with it an appetizing food and by spreading the mixture over a large surface. Honey has given poor results. The *Scientific American* says the best mixture is made with milk. It recommends a solution containing 15 per cent. of the formalin of commerce, 20 per cent. of milk, and 65 per cent. of water, placed in large flat vessels. Most of the dead flies fall, not within the vessels, but around them, sometimes at a great distance.

INDICANURIA AND ITS SIGNIFICANCE *

JUDSON DALAND, M.D.
Professor of Clinical Medicine at the Medico-Chirurgical College, and Physician to the Medico-Chirurgical Hospital
PHILADELPHIA

Indicanuria is the presence in the urine of a perceptible quantity, more than a mere trace, of the indoxyl sulphate of potassium, of which the chemical formula is $C_8H_6NKSO_4$. It is derived from anaerobic bacterial putrefaction of proteids.

Indol is first produced, and, at the time of absorption, is converted into a soluble indoxyl, which, in the juices of the body, unites with a base, usually potassium, and is excreted in the urine as indoxyl sulphate of potassium. Normally, from 5 mg. to 20 mg. of this substance are excreted daily; abnormally, from 50 mg. to 150 mg.

Numerous tests, most of which I have examined, have been offered for the determination of the presence of indican. The solution of the neutral or basic subacetate of lead, commonly employed to clear the urine, is not without disadvantage. Sometimes it removes a portion of the indican; occasionally it renders the detection easy. As an oxidizing agent a 1 per cent. solution of potassium chlorate is to be preferred to the solution of chlorinated soda, because of the instability of the latter.

The test for indican which is advised is as follows:

To 10 c.c. of filtered urine add one drop of a 1 per cent. solution of potassium chlorate; then add 5 c.c. of chloroform, and lastly 10 c.c. of pure hydrochloric acid of a specific gravity of 1.19. Thorough mixing is obtained by repeatedly and slowly pouring from one test-tube to another. The indigo thus set free is dissolved in the chloroform, to which is imparted a blue color. The maximum coloration is secured in ten minutes. When large amounts of indican are present, more potassium chlorate will be required.

Clinically, a quantitative idea of the amount of indican present may be obtained by noting the depth of the blue color of the chloroform. Salkowski, Strauss and others have devised methods by which the quantity of indican may be estimated, but most clinicians employ the qualitative method. The presence of a faint bluish discoloration of the chloroform may be viewed as normal or as possessing no importance. If the urine contains iodid the chloroform will be colored violet, which color may be removed by adding three drops of a 5 per cent. solution of sodium thiosulphate. Certain observers have noted that indican is usually absent in normal children under five years of age. Indican may be constantly present in large, moderate or small quantities, or only occasionally present during certain hours of the day or certain days of the week or month. In order, therefore, that the presence of indicanuria be not overlooked it is necessary to obtain urine for examination at different times during the day or week, or under conditions produced by variations in food, exercise, or during the presence of one of the most marked symptoms of this affection, as for example, headache. Indican is often detected in the urine passed after supper (care being taken to instruct the patient to empty the bladder before beginning the meal) and may be absent at all other times. Occasionally it may be necessary to modify the articles of food composing the supper, so as to make it a test meal. The urine first passed on arising and retiring, as well as that taken from a twenty-four-hour specimen, should always be examined. Sometimes indican is observed only after the ingestion of certain articles of food, or combinations of food, which may be indigestible, unsuitable or in excess. It must always be remembered that, owing to an idiosyncrasy, certain patients suffer acute indigestion with marked toxic symptoms, when they partake of certain foods or combination of foods which may for others be digestible.

Clinically, indicanuria may be mild or severe, acute, chronic, or recurrent, and occurs as an independent affection or as a complication of other diseases. The severe forms of intestinal toxemia simulate cholera and may cause death in less than one week.

Indicanuria is significant of the absorption of the products of putrefaction, which putrefactive material is usually situated in the gastrointestinal tract, but under exceptional circumstances may be in other parts of the body. It is well known that during putrefaction, phenol, cresol, fatty acids and gases, and other substances are elaborated, in addition to indol, skatol or methyl indol. The test for indican is so simple and the test for other putrefactive products so difficult that gradually indican has assumed the position of an indicator of the absorption, not only of indoxyl, but in addition any one or any combination of the bodies produced by the decomposition of proteids.

Indicanuria may be absent when proteid decomposition is present if absorption is prevented, and it is conceivable that intestinal toxemia occurs in the absence of indicanuria.

Indol is a volatile aromatic substance of fecal odor, crystallizing in white glancing crystals, is practically insoluble, and as it passes through the mucous membrane it is converted into soluble indoxyl and is carried by the portal blood to the liver, where it becomes indoxyl sulphate and later the indoxyl sulphate of potassium. When indican appears in the general circulation it is excreted as such by the kidneys.

Jaffé states that the subcutaneous injection of indol is followed by the appearance in the urine of large quantities of conjugated indoxyl compound. Herter maintains that indol is only moderately toxic to man and that small doses may produce frontal headache, mental irritability, insomnia and mental confusion, and that the continual absorption of enough indol to yield a constant strong reaction of indican in the urine is capable of inducing symptoms of neurasthenia. Skatol is supposed to act as does indol.

Phenol is extremely poisonous, but phenol-sulphate is non-toxic. Phenol is usually coexistent with indican and is increased and decreased in like manner, the principal exception being in anemia and cachexia, in which indican is increased and phenol is decreased, and in hunger, in which phenol is increased and indican is decreased. Cresol is supposed to act as does phenol.

During proteid decomposition of fatty acids, such as formic, acetic and propionic, are formed, and also certain gases, such as carbon dioxid, hydrogen, marsh gas and sulphuretted hydrogen. These acids are probably but moderately toxic in the quantities in which they exist under ordinary conditions; but it must not be forgotten that small quantities of sulphuretted hydrogen are extremely poisonous. On one occasion I administered per rectum sulphuretted hydrogen, which produced simultaneously rapid, intermittent, weak pulse, collapse, delirium, and a slight odor of this gas in the breath. These symptoms vanished in a few moments.

It is not improbable that in certain cases unknown or undiscoverable toxalbumins are formed which may be peculiarly poisonous even in very small quantities. No

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

exact knowledge exists as to the precise manner in which the body protects itself from the poisonous compounds produced during proteid decomposition, but it is believed that such an influence is exerted by the cells of the liver and intestinal mucous membrane. Baumann was able to demonstrate that the liver contains a larger amount of ethereal sulphates than does the blood. Clinically, indicanuria occurs more readily when the hepatic function is disturbed than when this organ is normal. Indicanuria not infrequently exists without symptoms. Occasionally putrefactive bodies are produced that are but slightly toxic, and certain individuals possess an inherited or acquired immunity, while others are peculiarly susceptible to very small quantities of these bodies. As it is unsafe to assume, in the light of our present knowledge, that indicanuria produces no harm when symptoms are absent, prudence dictates the prevention of its formation.

The conditions which favor indicanuria are numerous and demand attention. Morbid conditions of the teeth, mouth, oropharynx, nose and sinuses connected therewith, in their relation to the production of indol, possess an importance which is far too little recognized. Not infrequently the buccal cavity contains much decomposing material, together with many micro-organisms, both fermentative and putrefactive. The odor often suggests decomposition and examination may reveal abscess of the gums, pyorrhea alveolaris, with soft, flabby, congested and contracted gums, forming numerous cavities, in which pus and food may be retained under conditions peculiarly favorable to decomposition. A similar condition may arise fro [illegible] presence of food between the teet [illegible] is irregular dentition or caries. [illegible] rged crypts of diseased tonsils decomposing cheesy material may be found and suppurative rhinitis or sinusitis is not uncommon. When such conditions of the oropharynx, nose or sinuses exist it is manifest that food, even during mastication and before deglutition, may become infected and putrefaction begin.

Many causes favor the production of indol, such as simple excess of proteids from gormandizing; insufficient mastication or insalivation and too rapid eating; any condition paralyzing or lessening gastric, intestinal or colonic peristalsis, or retarding the onward progress of the gastrointestinal contents or interfering with the normal secretions of the stomach, intestines, pancreas or liver, etc. It is evident, therefore, that indicanuria is to be expected in gastrointestinal or colonic atony or paralysis as well as in relaxation of the abdominal wall, producing gastroptosis or enteroptosis. Again, hernia, ileus, appendicitis, local or general, acute or chronic peritonitis and pyloric or intestinal stenosis, constitute conditions favoring the growth of putrefactive bacteria.

The absence, diminution or excess of hydrochloric acid, by producing indigestion and fermentation, favor the production of indol.

Indicanuria has been observed in diarrhea, in association with indigestion, gastritis, enteritis, colitis, ulceration or obstruction of the small or large intestines, cholera, dysentery, Addison's disease and inanition. The deep importance of the [illegible] canuria as a complication in typhoid [illegible] in 1904, in a communication read before the Pennsylvania State Medical Society.

Constipation may exist without indicanuria, but is exceptional. Normal feces, the product of normal digestion in a normal individual, may remain in the colon an undue length of time without toxicity. Acute attacks of indigestion with furred tongue, offensive breath, constipation, mental and physical depression and headache, familiarly known as "biliousness" or congestion of the liver, are usually associated with indicanuria, and, in many instances, are examples of acute toxemia due to absorption of products of decomposition of the intestinal contents. It is more than probable that minor attacks of toxicity occur without well-marked symptoms. Recurring attacks of simple hepatic congestion, due to toxic poisoning, interfere with the normal excretion of bile, which in turn incites intestinal indigestion, fermentation and putrefaction, thus preparing the way for a similar attack on slighter provocation. In the course of months a chronic congestion of the liver is produced, aggravated by recurrent attacks of acute congestion, and thus, if the toxemia be moderate, in the course of years the clinical picture of hepatic cirrhosis may be developed.

Excessive formation of indol has been observed in various morbid states of the liver, with or without jaundice, in diseases of the pancreas, as well as in suppurative and gangrenous conditions of other parts of the body, as, for example, in empyema, gangrene or abscess of the lung and perityphlitic abscess; and has also been observed after the administration of turpentine or creosote.

Having thus far treated of indican as an indicator of toxemia, let us now turn to the various effects of toxemia.

Acute attacks of toxemia are frequently associated with dark-colored urine showing hyperacidity, high specific gravity, indicanuria and skatoluria, or moderate albuminuria and choluria, cylindroids and a few hyaline tube casts. As the toxemia increases in frequency and intensity, or becomes chronic with exacerbations, the albuminuria and cylindruria increase, and eventually, in consequence of long-continued irritation of the kidneys produced by the excretion of chemical irritants, resulting from intestinal putrefaction, chronic interstitial and parenchymatous nephritis develop. In the early stages, under appropriate treatment, these abnormal constituents in the urine disappear; again, in moderately severe cases, three, four or five years may elapse before this result is obtained.

The circulation in the blood of the derivatives of putrefaction absorbed from the intestines produces varying degrees of anemia, which, as a rule, is of the chlorotic type, and in long-standing and severe cases this anemia may become so extreme as closely to simulate the clinical and blood picture of pernicious anemia. The poison causes a rapid loss of hemoglobin and a slow loss of erythrocytes, but does not materially interfere with the leucocytes.

The circulation in the blood of these toxic substances at irregular intervals over a period of many years may cause the development of arteriosclerosis from direct action on the walls of the vessels. In a number of cases the conclusion was irresistible that this was the cause of arteriosclerosis.

The relationship of indicanuria to the nervous system is varied and most interesting. Several cases of neuroretinitis, associated with persistent and marked indicanuria, have gradually subsided and then disappeared, when this chronic poisoning was prevented; and in like manner, neuralgia or inflammation of other nerves have been produced. Occasionally pains in various parts of the body, due to intestinal toxemia, have been erroneously ascribed to rheumatism or gout. One of the common symptoms of acute or chronic intestinal toxemia is headache, either mild or severe, usually frontal, although it may be in the vertex or occiput. The duration varies from a few hours to a few days and may occur at intervals of two or three days, or as many weeks or months. An intermittent headache from this cause may continue unrecognized for months, and in one instance has been endured for seventeen years. Intestinal toxemia is as frequent a cause of headache as errors of refraction. Several examples of persistent insomnia, chiefly due to putrefactive poisoning, have come under my observation during the past decade. Certain individuals are peculiarly susceptible to minute quantities of putrefactive poison; this peculiarity has been especially observed among neurasthenics, in this respect resembling the well-known idiosyncrasy to alkaloids, such as atropin, etc. Chronic intestinal toxemia may induce or complicate cases of neurasthenia. It is not improbable that one of the reasons for the favorable results obtained from the use of a milk diet in treatment of neurasthenia is the incidental removal of an unrecognized toxemia.

Again, intestinal toxemia is a common complication of the various forms of mental diseases as seen at the Philadelphia Hospital, and occasionally it is the cause or complication of certain cases of epileptiform convulsions. The favorable course of many cases of pulmonary tuberculosis is interrupted by attacks of intestinal toxemia, and has been more frequently observed since the treatment of tuberculosis by large quantities of milk and eggs has become more general. The diagnosis of this complication is absolutely necessary for success in treatment of tuberculosis where a specific diet, suitable for the individual, should be substituted for the one in more general use. Putrefactive poisoning aggravates catarrhal inflammations of the respiratory tract and the recognition and removal of this complication is frequently followed by a marked amelioration of symptoms, and in like manner certain cases of bronchial asthma are greatly benefited. Eczema, pruritus, acne rosacea, and malodorous perspiration and breath have been observed in association with indicanuria.

Intestinal toxemia is a common disease in itself and a frequent complication of many diseases; its removal is very frequently followed by remarkable and prompt amelioration or disappearance of many distressing symptoms.

317 South Eighteenth Street.

ABSTRACT OF DISCUSSION

Dr. Heinrich Stern, New York: The pathologic significance of urinary indican, or rather indoxyl-sulphuric acid, has been grossly exaggerated. True, there ensues an increased production of indoxyl compounds in cholera, Addison's disease, obstructive affections of the small intestines, etc., but this does not justify us in ascribing to them toxic qualities, and to maintain that they stand at the foundation of a number of pathologic conditions. Of course, the indoxyl compounds have no direct relationship to so-called pyorrhea alveolaris, they are neither its cause nor its result. The indoxyl compounds are normal urinary constituents and we find them in small amounts in every human urine, except in that of new-born and breast-fed infants. Indoxyl is even contained in the renal secretion of infants who obtain besides human milk also some cow's milk and even in these instances, it occurs in the absence of any digestive disturbances whatsoever. Increased amounts of indoxyl as found in the urine allow of but one interpretation, namely, that we are confronted with some form of tryptic perversion. Some observers hold that the trypsin of the pancreatic secretion induces or favors the production of indoxyl. Their contention is based on two facts, viz.: the tryptic quality as regards decomposition of the ingested proteid material, and the decrease of urinary indoxyl in case of an occlusion of the pancreatic duct. Clinical experiments and observations, however, have demonstrated to my satisfaction that in the majority of instances of so-called indicanuria, we have to deal with an insufficiency of tryptic function and, consequently, with abnormal putrefactive processes and the augmentation of the intestinal bacterial flora. While it is, of course, possible that an indicanuria may occur with a process like pyorrhea alveolaris while it is even possible, although it has never been proved, that perverse intestinal putrefaction may stand in some more or less remote relationship to pyorrhea alveolaris, we have no business to maintain that one of the accidental products of such putrefaction, the indoxyl, is the true causative agent of this or of any other affection. We must not forget that pyorrhea alveolaris is an exceedingly progressive, chronic affection, and that indicanuria, that is the excessive excretion of indoxyl compounds, is essentially an acute, or at least, a limited occurrence. Is it possible that the rather ephemeral indicanuria will give occasion to the enduring pyorrhea? The same contention holds good with all other affections which, at one time or another, have been accused of having excessive excretion of indoxyl as their causative factor. The indoxyl compounds are not toxic in themselves, so far as we know, they are of more or less accidental occurrence, and may point to an occlusion of the small intestine with a decrease of tryptic function and an increase of bacterial activity. Everything else belongs to the realm of speculation. Moreover, I wish to direct attention to the fact that indoxyl occurs not only in the urine of carniverous but also in that of herbiverous animals. As a matter of fact, it is present in the urine of some of the herbivora in much larger quantities than in any of the carnivora. It occurrs in enormous amounts in the urine of the horse, from which we obtain it for experimental purposes. It may also be prepared from the urine of the dog, but, in my experience it is purer when it is derived from horse's urine. In the latter, it is present in larger proportion than in that of cattle. The reason for this seems to be the large cecum of the horse which permits additional and more complete disintegration of the ingested material. Indoxyl does not occur in the urine of the rabbit, as a general rule, but I have found it therein in the presence of artificially induced obstipation. While indoxyl appears in the urine in larger amounts after a diet rich in animal food, it never attains pathologically that proportion in the human being which is normally present in the urine of the horse. This evinces, I dare say, that animal food and the ensuing putrefactive processes, in herbivorous animals at least, are not the only source of indoxyl compounds and that vegetable ingesta and fermentative processes may give rise to indican production. I have employed for some time the potassium chlorate-chloroform-hydrochloric acid test advocated by Dr. Daland for clinical work.

Dr. Henry R. Harrower, Chicago: The subject under discussion appears to be unquestionably the entering wedge to even more important and vital studies. Dr. Daland has rightly emphasized the significance of indicanuria and its importance as an etiologic factor in disease. A point which I wish to emphasize, however, is the close relation between indicanuria and diseases of the mouth and teeth. As a matter of fact, mouth symptoms are among the first manifestations of those disturbances due to or associated with indicanuria and its causes. Acid saliva, pyorrhea and affections of the alveolar process are almost invariably accompanied by indicanuria. The pioneer work in this particular line of Dr. Eugene S. Talbot of Chicago proved this assertion. Acidemia is also frequently found associated with indicanuria; I do not refer to the acidosis of diabetes. In a series of several hundred uranalyses the average acidity was increased considerably, varying from 10° to 275°, the normal degree of acidity being from 30° to 40°. Each degree represents the amount of N/10 sodium hydrate required to neutralize 100 c.c. of urine. The number of acid units (and, by the way, this is an important factor recently suggested by Dr. A. L. Benedict of Buffalo) varied from about 8,000 to 350,000 in twenty-four hours, 40,000 being approximately the normal. In 83 per cent. of these cases indican was present to a greater or less extent, those cases showing an excess of indican always giving a marked increase in acidity. A number of cases showing indigo red instead of indigo blue all evidenced a tremendous acidity. In 81 per cent. of this series the urea index was diminished an average of one-half; in one case in which the acidity reached 220 and indican was abundant the percentage of urea was only 0.4 (2.8 gm. in twenty-four hours). About one-third of these cases showed casts. Summing up these facts it will be seen that indicanuria is practically always associated with an excessive elimination of acid substances in the urine and a marked decrease in the amount of urea, two very important findings. I believe that the condition of acidemia or diminished blood alkalinity is of far greater importance than present medical opinion or the text-books would lead one to believe; that it is a probable cause of many obscure diseases and consequently deserves more extended attention and thorough investigation. Further, the reduction of this condition of excessive acidity by the judicious use of suitable remedies brings with it a speedy and decided amelioration of many indefinable ills.

Dr. Richard C. Cabot, Boston: After using the test for indican for a long time in different clinical conditions, I have given it up and I would advise others to give it up. We sometimes get an increase of indican in the urine in pathologic conditions, of course; but in such case the nature of the pathologic condition present is much more obviously indicated from the clinical side. Indicanuria gives us no diagnostic or therapeutic indication. What was the relation of indicanuria and indican production to the diseases Dr. Daland mentioned?

Dr. Allen A. Jones, Buffalo: I think that Dr. Daland has mentioned two points in particular that are worthy of our consideration. The first is that normally from 25 to 50 grams of indican are excreted in twenty-four hours; whereas, abnormally from 50 to 150 are excreted. So I believe that it should be routine work to estimate the amount of indican excreted in twenty-four hours. The indican test has been employed in my laboratory for many years, using the qualitative but not the quantitative test. It may be that by using the quantitative test one may arrive at some definie clinical conclusions. So far as the qualitative test is concerned, very little attention is paid to it at the present time in a routine way except in the laboratories. Years ago an attempt was made to associate indicanuria with a definite condition of the stomach, a diminution of the amount of hydrochloric acid in the gastric contents; in my series of 160 cases, I could not prove any definite relation between the amount of secretion of hydrochloric acid and indicanuria, which was found with and without any diminution in the amount of hydrochloric acid in the gastric contents.

So far as can be gained from Dr. Daland's paper, we can come to but one general conclusion, *i. e.*, indicanuria is merely an evidence or symptom of a toxemia, and this toxemia may come from a variety of conditions. It is not associated with any definite pathologic condition in the body, or in other words, any definite disease.

Dr. Anthony Bassler, New York: My experience is confirmatory of Dr. Jones' statement concerning the relationship existing between states of gastric juice secretion and indicanuria. It is generally taught that the regular association with indicanuria is a low state of gastric juice secretion, but this is not always so. A marked indicanuria may exist with excess stomach secretion. Clinically speaking, I do not think that the indicanuric conditions are only produced by hypochlorhydria and anachlorhydria, but believe that the intestinal conditions called indicanuria often cause depression of the secretory apparatus of the stomach, for by the direct treatment of the intestinal condition its effects on the stomach are often mitigated or removed. I regret that Dr. Daland did not have time to describe his test, and I wish he would add whether the use of the solution he advocates will also give the uroresin reaction, which to me is just as important as indican.

Dr. Judson Daland, Philadelphia: I think that Dr. Jones' understanding of indicanuria is the correct one, namely that it is simply an indicator of the absorption of putrefactive substances, a certain toxemia. Much benefit is derived from the study of the presence of indican in the urine. To me, at least, it has been of great service. Indicanuria serves to aggravate certain conditions. To show this, I recall two cases of retinitis under the care of a skilled ophthalmologist, who found that the condition was toxic. Indican was present in the urine in large amounts. By successfully treating the indicanuria the patient made a good and rapid recovery from his retinitis. We can always take exceptions to clinical evidences; but clinical evidence is necessary because we are not in a position to offer experimental evidence. I have had the opportunity of watching the renal secretions under many conditions in association with indicanuria, and I have observed its disappearance followed by a clearing up of the evidences which make some believe there is an involvement of the kidney. I desire to repeat that indican itself is not a substance capable of producing any material interference with health; but in those conditions in which there is the continued presence of a large amount of indican I have found associated evidences of disorders of various parts of the body which, in my opinion, were due to the formation in the intestine of toxic substances of different kinds which I am unable to differentiate. Therefore, I use this test as a rough clinical method; when indicanuria is present, by causing the removal of the indican from the urine we improve the patient very materially. This is merely a clinical contribution. I was especially glad to hear Dr. Harrower speak of the condition of acidemia or diminished blood alkalinity.

CARDIAC AND VASCULAR COMPLICATIONS IN PNEUMONIA

WITH SPECIAL REFERENCE TO TREATMENT *

F. FORCHHEIMER, M.D.
CINCINNATI

If we glance at the etiologic conceptions which formerly existed in connection with lobar pneumonia—and unless otherwise stated lobar pneumonia is the only form of pneumonia referred to in this paper—it will not be difficult to see why the heart was neglected. Those who believed in a humoral origin of the disease assumed that the only thing requisite for the cure of pneumonia was blood-letting, and that it was not necessary to look to the heart. Indeed, with Bouillaud's formula of bleeding (1830), *coup sur coup* and withdrawing twelve to sixteen ounces at a time, the heart was literally neglected. Then came a time when bleeding was restricted to cases which presented some indication for it, although, as Trousseau says, most physicians and all the laity could not conceive of pneumonia patients recovering without it. The indication was not stated precisely, but more or less vaguely as, with Trousseau, general congestion. About the same time (1847) Skoda and Dietl (1847) pointed out the dangers, as well as the inutility, of the procedure in any case of pneumonia and substituted for it that which has been called the expectant treatment, or better, nihilistic treatment, which, however, was followed by more recoveries than had ever followed bleeding.

It was not until 1874, when von Jürgensen wrote his remarkable article,[1] that the heart was brought into prominence; he says: "The danger to life which croupous pneumonia produces in the patient first threatens the heart. Pneumonia death is caused by cardiac insufficiency." In this article, which in some ways is almost prophetic, he says, "Sine pulsu nulla therapia," thus differentiating pneumonia from typhoid fever, in which there is no treatment without the thermometer. Furthermore, among many other things now accepted, von Jürgensen recommends the fresh-air treatment, which has been so successfully rediscovered within the last few years.

[1] In von Ziemmsen's Handbuch der speciellen Pathologie und Therapie, vol. v, part 2

About ten years after this (1884-5) A. Fraenkel discovered the cause of lobar pneumonia, namely, Fraenkel's diplococcus, the *micrococcus lanceolatus*, or as Fraenkel himself calls it, the pneumococcus. From this time our expectations of increased knowledge were fulfilled. For clinical and therapeutic purposes many things have been added, for the study of blood-vessel conditions the most important is found in Romberg and Pässler's contribution [2] on the effect of pneumonia infection on the general circulation. These two observers showed that the toxic albuminoid which is produced during metabolic activity of the pneumococcus paralyzes the vasomotor center in the medulla oblongata, and Pässler, in a subsequent communication[3] states that this is the most common cause of death in pneumonia, in as far as the circulatory apparatus alone is concerned. The objections to the complete acceptance of this view were that there was the incomplete accordance of experimental results and clinical observation, and that the condition had not been identified in man. At the present day the first may be considered as having been satisfactorily settled; for the second, although identification is fairly complete, much more must be done in order that the clinical picture may be accepted by the profession at large. I do not hesitate to state that with a healthy heart vasomotor paralysis is the most common cause of pneumonia death, in so far as the cardiovascular apparatus is concerned, and it goes without saying that this mode of death may occur irrespective of health or disease of the heart. As a matter of fact, there is still some doubt whether, with sufficient infection to produce this vasomotor condition, the heart muscle is not always affected and whether the former or the latter develops first.

Long ago it has been shown in animals that, on section of the splanchnic nerve, an enormous quantity of blood accumulates in the intestine, which is followed by intense anemia in other organs, especially in the central nervous system, which may cause death. The splanchnic nerve is the vasomotor nerve of the intestines, and its section causes paralysis of vasomotor function and enormous dilatation of blood-vessels. In paralyzing the vasomotor center with the pneumococcus the same result follows in man. In brief, in man there is first, dilatation of blood-vessels in the splanchnic area; the blood-pressure, which sooner or later is normally low in pneumonia, sinks; the heart, which is supplied by an insufficient quantity of blood, which is gradually becoming stationary in the affected area, continues to draw blood from other places, the liver, the skin, the muscles and central nervous system, and becomes more and more rapid and ineffectual, "bleeding itself into the splanchnic area," and finally stops. The intracardiac pressure is reduced so that the myocardium ceases to contract; moreover, the various cardiac and vasomotor centers become asphyxiated, and therefore paralyzed.

All this, as Pässler first pointed out, produces a characteristic clinical picture. My observation has led me to add to his description, so that it presents itself as follows: The first evidences are rapidity of heart and sinking of blood-pressure; with this, or shortly afterward, there comes tympanites; the patient then presents an exsanguinated appearance, with beginning evidences of collapse; the pulse becomes irregular, empty and so rapid that it cannot be counted; symptoms of cerebral anemia begin to appear—delirium, hallucinations, sometimes great restlessness; they gradually disappear to be superseded by stupor and coma; the collapse increases; the heart becomes more irregular; the heart sounds disappear, and the patient dies.

With such an appalling possibility staring us in the face in every case of pneumonia (for we are not in a condition to determine when the infection is sufficient to produce the condition described), it would seem natural to resort to means in order that its development may be prevented. In order to accomplish this purpose A. Fraenkel[4] recommends the administration of digitalis. He gives ¾ gm. a day for three or four days, maximum 12 gm. in all, in all cases which come under observation within the first three days of the disease. It is contraindicated in patients with organic disease of the heart, kidneys or blood-vessels, and he does not apply this mode of treatment in drinkers and patients over 50 years of age. His results seem to be satisfactory; the temperature sinks; the pulse does not become more rapid and the blood-pressure never diminishes. Theoretically there can be no objection to this mode of treatment, but my own experience with it has not convinced me that it is the best. In 1891 Petresco[5] of Bucharest published an article on the treatment of pneumonia with large doses of digitalis in which he recommends the administration daily of 4-8 gm. of digitalis infusion given in twenty-four hours, according to the severity of the case. In some cases he gave as much as 24 gm. in four to five days. As there was an epidemic of pneumonia in my wards at the time of the appearance of this publication, all the patients were put on this treatment. I failed to verify nearly all of his conclusions, even to the small detail that the pulse fell after one to three doses had been given. On the contrary, mortality was greater than before. All the evil effects that can be produced by digitalis were noted, and after three days of administration of the remedy such cumulative effects were produced as I shall hope never to see again.

The next remedy which I tried was the routine administration of strychnin; while I should not want to be without it in the acute infections, it does not prevent the vasomotor syndrome which is under consideration.

Because of the peculiar action of caffein, in stimulating the vasomotor center and its action on the heart, I have administered this drug for the last twelve years in a routine way. Caffein always increases blood-pressure, unless there is some organic lesion which in and of itself produces increased blood-pressure. Thus, in nephritis, when the pressure is abnormally high, it is doubtful if the pressure goes higher on administration of caffein, but the presence of this complication is, it seems to me, an additional reason for giving the drug.

In aortic sclerosis and splanchnic sclerosis caffein may be given with safety when the blood-pressure is below normal, or when it sinks. In all organic heart lesions it is also safe. So that the only contraindication for its use would be abnormally high blood-pressure, when there is danger of doing harm by the possibility of increasing it, a condition which may present itself in cases of cerebral arteriosclerosis, or in recent endocarditis. I have never seen any other effect on the heart than diminution in rate in pneumonia when the drug is given in proper doses. For prophylactic purposes it is not necessary to give more than 0.10

to 0.30 gm.—(gr. i ss to v) every four hours. When the symptoms of "bleeding into the splanchnic area" have developed it should be given hypodermically 0.20 gm. three or four times daily. I employ the double salts (preferably the caffein-sodiosalicylate because it is best made in this country), as they are more stable when dissolved in water, more soluble and less irritating when administered hypodermically than any of the other salts of caffein. On the whole, they do exactly what Fraenkel has claimed for digitalis; they reduce the pulse-rate, the fever may become reduced; they increase the blood-pressure; they reduce the mortality without being subjected to many limitations in administration and without producing the unpleasant effects of digitalis when given in proper dosage. Occasionally it occurs that patients become nervous and sleepless, which is remedied by reduction of dose.

Other preventive measures of great importance should also be considered. First among them I would place the fresh-air treatment, which reduces wear and tear, rendering all patients less liable to fatigue and which also lessens toxemia. Next to this, I would emphasize the necessity of treating sleeplessness from whatever cause it may arise; the continuance of wakefulness is very dangerous, both for the nervous system and for the heart, and as von Jürgensen says, "there are cases in which the whole therapeutic problem temporarily reduces itself to the production of sleep." Lastly, it may become necessary, in individual cases to reduce the temperature. I have purposely said "individual cases," as antithermic treatment is not necessary, as a rule. When the temperature produces damage it should be reduced, but only by such measures as do no harm, and especially do no harm to the heart.

The Nauheim or calcium chlorid baths, as recommended by P. K. Brown,[6] in vasomotor paresis in acute infectious diseases might be advantageously employed instead of the ordinary cool or cold bath, especially as a preventive measure. Besides these, all those other dietetic, hygienic and therapeutic measures and the proper treatment of other symptoms must be considered as acting prophylactically, notably those which may affect the central nervous system unfavorably.

When the symptom-complex has developed then most energetic measures should be adopted. In 1898 I was successful in arresting a case of splanchnic vasomotor paralysis, and in 1904, after having had a number of cases, two of which were in children, I published the method[7] which had been successful. It is as follows: Adrenalin is employed for the purpose of contracting the blood-vessels of the spanchnic area, for which, according to Abel, it has an elective affinity; hypodermoclysis or venous transfusion with large quantities of normal saline solution (0.90 per cent. Hamburger) for the prevention of asystole, one or two ice-bags on the abdomen which reduce the pulse, probably by stimulation of a splanchnic reflex. Adrenals were first recommended in pneumonia by E. A. Gray[8] in 1902. Henry L. Elsner[9] recommends adrenalin for vasomotor paralysis for precisely the same reason as stated above. Adrenalin may be given with the hypodermoclysis, 1 c.c. of a 1000 solution; the frequency of its application must depend on the symptoms, as its effects are transitory. This is one of the few conditions in which a physician should be "in constant attendance." According to the rate and rhythm of the pulse, which are entirely satisfactory indices, even without blood-pressure estimations in the onset, the drug should be administered every two to four hours. This cannot be kept up very long, so that I have found it necessary to give hypodermic injections of caffein to take the place of the hypodermoclysis, which usually results in giving three or four saline and adrenalin injections a day and four doses of caffein. In the first twenty-four to thirty-six hours most reliance should be placed on hypodermoclysis; with the added adrenalin gradually the caffein is allowed to take its place. The ice-bags are valuable adjuncts; in one patient, without any other treatment, I succeeded in reducing the pulse-rate from 140 to 60 per minute. As soon as such an effect is produced, or when tympanites disappears, the ice-bags should be discontinued, to be reapplied when the pulse goes up or the tympanites reappears. This mode of treatment, applied in all kinds of vasomotor paralysis, has given me about 50 per cent. recoveries. Esser[10] has employed large doses of camphor hypodermically to increase blood-pressure; in one case he gave 23 gm. (345 grains) in four days. He lost 2 cases out of 13—but his record is not perfectly clear, as 2 cases, at least, belonged to another type of heart failure.

The subject of dilatation of the right heart as a menace in pneumonia has received considerable attention by modern writers. Those of us who have seen a great deal of pneumonia will admit that it is a rare occurrence. A. Fraenkel[4] states that it cannot be found in all serious cases. Petzold[11] records observations in 271 cases without having found it once. Pässler[3] claims that it may occur in rare instances from increased resistance in the pulmonary circulation. On the other hand, all pathologists point out the fact that after death the right chamber of the heart is distended by firm coagula. But, as it *is* admitted to exist by clinicians, it seems unnecessary, at this time, to discuss the apparent discrepancy between clinical and the pathologic-anatomic attitudes; we certainly must admit with A. Fraenkel that if the heart is not too unfavorably affected by toxic effects, resistance in the pulmonary circulation "is overcome without difficulty and without dilatation of the right heart in the greatest number of cases."

The clinical picture differs altogether from that produced by vasomotor paralysis. The patient is cyanotic; there is great dyspnea; increased activity of all the obligatory as well as accessory respiratory muscles, as well *as by* all the other evidences of dyspnea are present. On examination we find the jugular veins overfilled, the movements of the heart very much increased, especially those of the right ventricle; on percussion there is increased heart dulness to the right from 1 to 3 cm.; on auscultation there is accentuation of the second pulmonary sound which disappears as the case progresses. Frequently edema of the lungs is also found. The liver is usually enlarged; when the condition lasts for over twenty-four hours it is very much enlarged. The patient dies in asphyxia—never in collapse, unless this condition is combined with vasomotor paralysis. The simplest treatment of this condition is blood-letting by venesection, and ordinarily from eight to sixteen ounces should be drawn. Primarily the pulmonary circulation is relieved, and, secondarily, the dilatation of the right heart. If there is pulmonary edema this may also disappear; at all events when done properly, phlebotomy is followed by remarkable results, so remarkable, indeed, as to make one wonder if blood-letting has not become what Gross called it, a lost art. It is, however, not necessary to do this in every case. The mode of treatment which is applied in ordinary cases of acute myocardial insufficiency is usually sufficient. It consists of hypodermic injections of digitalin in large doses, of camphor and ether, of caffein. Alcohol is not indicated unless the patient is an alcoholic.

The other cardiac conditions which may develop in the healthy heart are pericarditis, acute myocarditis and endocarditis. Endocarditis is the most frequent complication, and the third most common cause for pericarditis is the pneumococus. In regard to acute myocarditis in pneumonia our knowledge is fragmentary. Without any other cause the frequency of pericarditis and endocarditis would lead one to imagine that acute myocarditis should also be present. But from what we know of the etiology of acute myocarditis this could not be final, as we find acute myocarditis in pneumonia, without either pericarditis or endocarditis. It seems, however, that acute myocarditis in pneumonia is the postfebrile form and as such leads to sudden death from acute myocardial insufficiency. Acute endocarditis is found as the simple and the septic form (malignant, ulcerative endocarditis). As pneumonia is a bacteriemia, it is not remarkable that the septic form develops with relative frequency. The treatment of these conditions is the same as is applied to them under other conditions.

From von Leyden's statement it seems that we in America, as well as the Russians, have taken to employing strychnin in the heart complications of pneumonia and, as he says, he also has employed it with benefit. As far as the heart is concerned, strychnin has an effect only in toxic doses. Indirectly given in normal doses it may, however, affect the heart by stimulating its inhibitory center, and, therefore, reducing its rate. It furthermore is followed by contraction of blood-vessels, but, in man, not sufficient to increase blood-pressure. As strychnin increases the irritability of the cord somewhat, many of the normal functions of the cord are increased in activity. Furthermore, it stimulates the respiratory center, in normal doses, but large doses are followed by paralysis. It would seem, then, that when we give large doses, so frequently administered in pneumonia in a routine way, we may stimulate the heart, but do great damage to the respiratory center. In small doses it is invaluable in pneumonia, in acute myocarditis, although it has also been given in enormous doses here with apparent success, but it is especially valuable as a stimulant of the respiratory center—indeed, as a stimulant of the whole cord. On the other hand, its routine administration, especially to the degree of producing toxic effects, should not be encouraged, as it does not prevent the accident we now most fear and, moreover, produces deleterious effects. Elsner[9] most forcibly states the position in regard to the administration of nitroglycerin in a healthy heart; we already have lowered blood-pressure; why should we increase it, and bring it to or beyond the danger line? It should not be given, even in overfilling of the right ventricle, as it especially affects the splanchnic area.

The treatment of pneumonia with coexisting heart disease has been variously described. Some authors give digitalis in every case, others only for specific indications. It would seem that as in routine administration of digitalis in any heart disease this drug might do harm, as it does when administered indiscriminately. With the present advance which we owe to modern pharmacy, in giving us reliable glucosids, acting when given in proper doses, either hypodermically or intravenously, with certainty and promptly, the preparation of the heart for a possible breakdown, which takes at least two days, is no longer necessary. At least such has been my experience in the last three or four years. In chronic valvular disease in which I always gave digitalis formerly I now restrict its administration to those cases in which there is a probability of decompensation because of the additional work put on the heart. The conditions may be summed up as follows, such as have already had decomposition or are having it when pneumonia develops, and, furthermore, in those valvular lesions in which compensation is not complete. Therefore, in all valvular lesions, except aortic or mitral insufficiency in which there is complete compensation, it is not wise to take chances.

With diseases of the myocardium we find, on the whole, the most dangerous complicated form of pneumonia; Pässler's statistics show that in pneumonia with chronic myocarditis the mortality is 93 per cent. While I believe this to be an exaggerated statement, because of the small number of cases which are considered, it is, nevertheless, true that chronic myocarditis is the greatest menace to life in patients with pneumonia. But here, as well as in all other forms of myocardial diseases, the degree of danger lies in the degree of existing chronic myocardial insufficiency. Any patient who goes into an attack of pneumonia with abnormally low blood-pressure due to chronic myocardial insufficiency has little chance for recovery.

Whenever any manifestation of myocardial insufficiency develops it should be treated as an acute myocardial insufficiency. The results naturally vary with the form of myocardial disease and with the individual condition. In the fat heart little can be expected from digitalis or strophanthus when the myocardium is already weak or there also exists arteriosclerosis. In the heart of Bright's disease when, notwithstanding the existence of heart disease, the blood-pressure goes down, caffein should be given in large doses and digitalis as well. In arteriosclerosis the blood pressure is an infallible guide to therapy; when it sinks the ordinary remedies should be applied; when it remains high it is not wise to give vasodilators. Myocardial disease due to other conditions, as chronic respiratory troubles, malformations of the thorax, etc., should be treated as all other chronic myocardial insufficiencies, in addition to which, at times, it may be possible to employ causal therapy.

Pericarditis does harm in two ways, either producing myocardial insufficiency by extension to the myocardium, by the production of adhesive processes or—which is rare—by the presence of fluid in the pericardial sac. When the latter exists the fluid should be removed; otherwise, the myocardial insufficiency should be treated.

ABSTRACT OF DISCUSSION

Dr. De Lancey Rochester, Buffalo: I regret that Dr. Forchheimer could not go into the details regarding the treatment of dilatation of the right heart, because that is one of the conditions that it is not uncommon in pneumonia; in fact, it is very common. It is one of the conditions in which venesection is particularly indicated. I can recall at present twelve cases of pneumonia with dilatation of the right heart, and in all of them I believe life was saved by doing a prompt venesection, withdrawing from 200 to 400 c.c. of blood. As illustrative of its value, I should like to report one case. This patient was 18 years old, and had had a progressive pneumonia involving one lobe after another, so that all the right lung and the upper lobe of the left as well as the pericardium were involved. The heart's apex was in the axillary line and the pulse was 180 or more, very irregular and small. The liver was two inches below the costal margin. There were present all the evidences of a dilated right heart. Flatness was complete on the right side, and it was feared that there might be fluid, and so the chest was aspirated in four directions, but nothing was found but solid lung. This patient was bled 250 c.c., and during the bleeding the respirations, which had been 66 to the minute, fell to 36; the pulse, which had been 180 and irregular and small, dropped to 120 and showed better tension. The heart, which had been in the axillary line moved to midway between the axillary and nipple lines in the fifth interspace and acted better. This patient's life was saved This illustrates one of the cases in which venesection was successful. It is a procedure which has gone into disrepute, but it should be used always when indicated.

Dr. Frank Billings, Chicago: We all agree with Dr. Forchheimer that active measures are necessary when the cardiovascular syndrome develops; until that time, we are not all agreed as to what we should do with such patients. I think there is no disease in which rare judgment is so necessary not only in knowing what to give, but in knowing when not to give drugs. From my own experience I find that the longer I live and attempt to cure patients with pneumonia, the less I am inclined to give mixtures containing drugs until they are necessarily called for, and this is especially true in hospital work. The moment that cardiovascular symptoms appear, with the lowered blood pressure, with failing left heart, the time has then come for active work. I believe in the proper use of digitalis, but not as ordinarily given and by the mouth. With the hypodermic use of digitalis I have had a sad experience; it was with the active principles of the drug, and now I practically never use them. But I do use a preparation of the leaves themselves.

In an emergency, the intravenous use of digitalis gives good results. When used in that way it is not necessary to repeat the dose unless symptoms indicate. Four, six, ten, twelve doses may be necessary, and perhaps one dose, in some instances, will accomplish all that is necessary.

There are other remedies besides digitalis which increase the ordinary tone. Caffein is a good agent and camphor will readily raise the blood-pressure in cases of failing left hearts. I give one or two-grain doses in ordinary camphorated oil. Musk also will raise the blood-pressure. Strychnin and other drugs that are commonly used in failing left heart are absolutely valueless except to stimulate nerve centers; strychnin will not raise the blood-pressure 1 mm. I have used it over and over again. If that unfortunate condition occurs, dilatation of the right heart, I think that venesection is the one remedy to be applied and immediately, and it matters not whether the patient be plethoric or not.

The use of cold applications to the chest I have followed. In failing heart the applications of bandages about the extremities is sometimes of value. But whatever is used must be used with good judgment or more harm than good may result.

Finally, the watchful and vigilant care of patients afflicted with pneumonia without the use of drugs is the ideal treatment. Do not attempt to do good by any specific medication, but attempt to preserve the functions of the individual's body, and do not be nihilistic regarding the use of remedies. I think we may say that with proper management of the patient we may occasionally save patients who might otherwise die.

Dr. C. F. Hoover, Cleveland: I wish to call attention to the danger of accepting a measurement of blood-pressure as an equivalent for the mass movement of blood. The fact that a patient has a maximum blood-pressure equal to a column of mercury 140 mm. high, does not justify the deduction that the mass movement of blood is satisfactory. Patients with severe mitral stenosis, for instance, may have a great disturbance in the blood distribution of the body with marked asystole, and still have a normal arterial pressure. The sphygmomanometer is not a safe guide in estimating the mass movement of blood. The position of the right border of cardiac dulness, the size of the liver, the pulsations in the internal jugular vein and the duration of the pulse in relation to the maximum systolic blood-pressure are all factors which must be considered in estimating circulatory efficiency. To estimate the size of the right auricle by percussion is one of the nicest refinements of physical diagnosis, and yet this very point is one which must be determined to settle the question of therapy in pneumonia if we are to anticipate an advanced cardiac incompetency with a suitable therapy.

Dr. John H. Musser, Philadelphia: It is very important that we should remember in those cases of apparent cardiac failure, that such cardiac failure is the result often of pericardial effusion. Too often do we see these patients treated for heart failure, or acute dilatation of the heart in the course of pneumonia when by removing a few ounces of fluid from the pericardial sac the serious symptoms are relieved.

Of course Dr. Forchheimer will agree that the best treatment of the heart is that which is applied in the first period of the disease, as soon as the pneumococcus infection is recognized. Therefore, the results that are to follow will depend on such form of management. I am in sympathy and in accord with what Dr. Billings stated. In the majority of the cases I prefer to rely on fresh air, on judicious local treatment, on hydrotherapeutics, on regulation of the proper amount of food taken, and particularly on care that the patient is not overfed. I watch carefully for the phenomena so well pictured by Dr. Forchheimer, guarding against the possibility of the vasomotor syndrome by proper renal elimination. Attention to proper elimination is of the greatest importance in the management of the cases of pneumonia, looking toward the prevention of cardiac failure; in other words, looking toward the reduction of serious toxic symptoms that arise and have expression more particularly in the phenomena just pointed out. To keep down the amount of food is of the greatest importance in the management of pneumonia patients. Watch carefully the state of the intestinal tract. Tympany is a serious toxic symptom in pneumonia and its increase with defective elimination is a point that I depend on as suggestive of the occurrence of vasomotor failure. This can be prevented very largely. Colitis occurs with the pneumococcus affection, and this colitis is undoubtedly the cause of the development of tympanitis; the colitis plus the toxemia invites an intestinal paresis. Hence to prevent this colitis which gives rise to the tympany, it is well to observe carefully the diet, regulating judiciously the amount and kind of food taken, and washing out the bowels with normal salt solution. Basing treatment on the idea that cardiac symptoms are threatened when renal insufficiency appears, I begin very early the use of caffein; this is perhaps the only remedy I would begin with as a routine measure. In addition I rely on cocain when the conditions become more extreme.

In regard to right-sided dilatation of the heart I agree with Dr. Rochester as to the value of early venesection. One must remember that we must not place too much stress on the physical signs brought out by percussion and auscultation. I am not so much disturbed by the development of murmurs suggestive of dilatation as I am of the appearance of vasomotor phenomena. I am not alarmed when asked to see cases of old valvulitis with mitral regurgitation. When we observe a murmur over the right heart, or a murmur at the apex, there comes into play the safety valve action of the tricuspid; this was pointed out long ago by Guiteras and often bodes much good in these cases.

Dr. Alexander Lambert, New York: Eight years ago I became dissatisfied with the results of the treatment of pneumonia that I had been following; they were very unsatisfactory and I decided that when a large number of pneumonia cases came into the hospital, as at Bellevue Hospital, it would be well to compare the results of different treatments carried on simultaneously. In my division at Bellevue Hospital (there are four divisions), I gave up the use of alcohol and nitroglycerin and simply used those drugs by which we obtain a rise in blood-pressure. After three months, when each division had had from 125 to 137 patients each, I found that in those cases where alcohol and nitroglycerin has been used, the statistics were 10 per cent. higher in death rates in which the vasodilators had been used than were shown by those in which the is followed by remarkable results, so remarkable, indeed, as to make one wonder if blood-letting has not become what Gross called it, a lost art. It is, however, not necessary to do this in every case. The mode of treatment which is applied in ordinary cases of acute myocardial insufficiency is usually sufficient. It consists of hypodermic injections of digitalin in large doses, of camphor and ether, of caffein. Alcohol is not indicated unless the patient is an alcoholic.

The other cardiac conditions which may develop in the healthy heart are pericarditis, acute myocarditis and endocarditis. Endocarditis is the most frequent complication, and the third most common cause for pericarditis is the pneumococcus. In regard to acute myocarditis in pneumonia our knowledge is fragmentary. Without any other cause the frequency of pericarditis and endocarditis would lead one to imagine that acute myocarditis should also be present. But from what we know of the etiology of acute myocarditis this could not be final, as we find acute myocarditis in pneumonia, without either pericarditis or endocarditis. It seems, however, that acute myocarditis in pneumonia is the postfebrile form and as such leads to sudden death from acute myocardial insufficiency. Acute endocarditis is found as the simple and the septic form (malignant, ulcerative endocarditis). As pneumonia is a bacteriemia, it is not remarkable that the septic form develops with relative frequency. The treatment of these conditions is the same as is applied to them under other conditions.

From von Leyden's statement it seems that we in America, as well as the Russians, have taken to employing strychnin in the heart complications of pneumonia and, as he says, he also has employed it with benefit. As far as the heart is concerned, strychnin has an effect only in toxic doses. Indirectly given in normal doses it may, however, affect the heart by stimulating its inhibitory center, and, therefore, reducing its rate. It furthermore is followed by contraction of blood-vessels, but, in man, not sufficient to increase blood-pressure. As strychnin increases the irritability of the cord somewhat, many of the normal functions of the cord are increased in activity. Furthermore, it stimulates the respiratory center, in normal doses, but large doses are followed by paralysis. It would seem, then, that when we give large doses, so frequently administered in pneumonia in a routine way, we may stimulate the heart, but do great damage to the respiratory center. In small doses it is invaluable in pneumonia, in acute myocarditis, although it has also been given in enormous doses here with apparent success, but it is especially valuable as a stimulant of the respiratory center—indeed, as a stimulant of the whole cord. On the other hand, its routine administration, especially to the degree of producing toxic effects, should not be encouraged, as it does not prevent the accident we now most fear and, moreover, produces deleterious effects. Elsner[9] most forcibly states the position in regard to the administration of nitroglycerin in a healthy heart; we already have lowered blood-pressure; why should we increase it, and bring it to or beyond the danger line? It should not be given, even in overfilling of the right ventricle, as it especially affects the splanchnic area.

The treatment of pneumonia with coexisting heart disease has been variously described. Some authors give digitalis in every case, others only for specific indications. It would seem that as in routine administration of digitalis in any heart disease this drug might do harm, as it does when administered indiscriminately. With the present advance which we owe to modern pharmacy, in giving us reliable glucosids, acting when given in proper doses, either hypodermically or intravenously, with certainty and promptly, the preparation of the heart for a possible breakdown, which takes at least two days, is no longer necessary. At least such has been my experience in the last three or four years. In chronic valvular disease in which I always gave digitalis formerly I now restrict its administration to those cases in which there is a probability of decompensation because of the additional work put on the heart. The conditions may be summed up as follows, such as have already had decomposition or are having it when pneumonia develops, and, furthermore, in those valvular lesions in which compensation is not complete. Therefore, in all valvular lesions, except aortic or mitral insufficiency in which there is complete compensation, it is not wise to take chances.

With diseases of the myocardium we find, on the whole, the most dangerous complicated form of pneumonia; Pässler's statistics show that in pneumonia with chronic myocarditis the mortality is 93 per cent. While I believe this to be an exaggerated statement, because of the small number of cases which are considered, it is, nevertheless, true that chronic myocarditis is the greatest menace to life in patients with pneumonia. But here, as well as in all other forms of myocardial diseases, the degree of danger lies in the degree of existing chronic myocardial insufficiency. Any patient who goes into an attack of pneumonia with abnormally low blood-pressure due to chronic myocardial insufficiency has little chance for recovery.

Whenever any manifestation of myocardial insufficiency develops it should be treated as an acute myocardial insufficiency. The results naturally vary with the form of myocardial disease and with the individual condition. In the fat heart little can be expected from digitalis or strophanthus when the myocardium is already weak or there also exists arteriosclerosis. In the heart of Bright's disease when, notwithstanding the existence of heart disease, the blood-pressure goes down, caffein should be given in large doses and digitalis as well. In arteriosclerosis the blood pressure is an infallible guide to therapy; when it sinks the ordinary remedies should be applied; when it remains high it is not wise to give vasodilators. Myocardial disease due to other conditions, as chronic respiratory troubles, malformations of the thorax, etc., should be treated as all other chronic myocardial insufficiencies, in addition to which, at times, it may be possible to employ causal therapy.

Pericarditis does harm in two ways, either producing myocardial insufficiency by extension to the myocardium, by the production of adhesive processes or—which is rare—by the presence of fluid in the pericardial sac. When the latter exists the fluid should be removed; otherwise, the myocardial insufficiency should be treated.

ABSTRACT OF DISCUSSION

DR. DE LANCEY ROCHESTER, Buffalo: I regret that Dr. Forchheimer could not go into the details regarding the treatment of dilatation of the right heart, because that is one of the conditions that it is not uncommon in pneumonia; in fact, it is very common. It is one of the conditions in which venesection is particularly indicated. I can recall at present twelve cases of pneumonia with dilatation of the right heart, and in all of them I believe life was saved by doing a prompt venesection, withdrawing from 200 to 400 c.c. of blood. As illustrative of its value, I should like to report one case. This patient was 18 years old, and had had a progressive pneumonia involving one lobe after another, so that all the right lung and the upper lobe of the left as well as the pericardium were involved. The heart's apex was in the axillary line and the pulse was 180 or more, very irregular and small. The liver was two inches below the costal margin. There were present all the evidences of a dilated right heart. Flatness was complete on the right side, and it was feared that there might be fluid, and so the chest was aspirated in four directions, but nothing was found but solid lung. This patient was bled 250 c.c., and during the bleeding the respirations, which had been 66 to the minute, fell to 36; the pulse, which had been 180 and irregular and small, dropped to 120 and showed better tension. The heart, which had been in the axillary line moved to midway between the axillary and nipple lines in the fifth interspace and acted better. This patient's life was saved This illustrates one of the cases in which venesection was successful. It is a procedure which has gone into disrepute, but it should be used always when indicated.

DR. FRANK BILLINGS, Chicago: We all agree with Dr. Forchheimer that active measures are necessary when the cardiovascular syndrome develops; until that time, we are not all agreed as to what we should do with such patients. I think there is no disease in which rare judgment is so necessary not only in knowing what to give, but in knowing when not to give drugs. From my own experience I find that the longer I live and attempt to cure patients with pneumonia, the less I am inclined to give mixtures containing drugs until they are necessarily called for, and this is especially true in hospital work. The moment that cardiovascular symptoms appear, with the lowered blood pressure, with failing left heart, the time has then come for active work. I believe in the proper use of digitalis, but not as ordinarily given and by the mouth. With the hypodermic use of digitalis I have had a sad experience; it was with the active principles of the drug, and now I practically never use them. But I do use a preparation of the leaves themselves.

In an emergency, the intravenous use of digitalis gives good results. When used in that way it is not necessary to repeat the dose unless symptoms indicate. Four, six, ten, twelve doses may be necessary, and perhaps one dose, in some instances, will accomplish all that is necessary.

There are other remedies besides digitalis which increase the ordinary tone. Caffein is a good agent and camphor will readily raise the blood-pressure in cases of failing left hearts. I give one or two-grain doses in ordinary camphorated oil. Musk also will raise the blood-pressure. Strychnin and other drugs that are commonly used in failing left heart are absolutely valueless except to stimulate nerve centers; strychnin will not raise the blood-pressure 1 mm. I have used it over and over again. If that unfortunate condition occurs, dilatation of the right heart, I think that venesection is the one remedy to be applied and immediately, and it matters not whether the patient be plethoric or not.

The use of cold applications to the chest I have followed. In failing heart the applications of bandages about the extremities is sometimes of value. But whatever is used must be used with good judgment or more harm than good may result.

Finally, the watchful and vigilant care of patients afflicted with pneumonia without the use of drugs is the ideal treatment. Do not attempt to do good by any specific medication, but attempt to preserve the functions of the individual's body, and do not be nihilistic regarding the use of remedies. I think we may say that with proper management of the patient we may occasionally save patients who might otherwise die.

DR. C. F. HOOVER, Cleveland: I wish to call attention to the danger of accepting a measurement of blood-pressure as an equivalent for the mass movement of blood. The fact that a patient has a maximum blood-pressure equal to a column of mercury 140 mm. high, does not justify the deduction that the mass movement of blood is satisfactory. Patients with severe mitral stenosis. for instance, may have a great disturbance in the blood distribution of the body with marked asystole, and still have a normal arterial pressure. The sphygmomanometer is not a safe guide in estimating the mass movement of blood. The position of the right border of cardiac dulness, the size of the liver, the pulsations in the internal jugular vein and the duration of the pulse in relation to the maximum systolic blood-pressure are all factors which must be considered in estimating circulatory efficiency. To estimate the size of the right auricle by percussion is one of the nicest refinements of physical diagnosis, and yet this very point is one which must be determined to settle the question of therapy in pneumonia if we are to anticipate an advanced cardiac incompetency with a suitable therapy.

DR. JOHN H. MUSSER, Philadelphia: It is very important that we should remember in those cases of apparent cardiac failure, that such cardiac failure is the result often of pericardial effusion. Too often do we see these patients treated for heart failure, or acute dilatation of the heart in the course of pneumonia when by removing a few ounces of fluid from the pericardial sac the serious symptoms are relieved.

Of course Dr. Forchheimer will agree that the best treatment of the heart is that which is applied in the first period of the disease, as soon as the pneumococcus infection is recognized. Therefore, the results that are to follow will depend on such form of management. I am in sympathy and in accord with what Dr. Billings stated. In the majority of the cases I prefer to rely on fresh air, on judicious local treatment, on hydrotherapeutics, on regulation of the proper amount of food taken, and particularly on care that the patient is not overfed. I watch carefully for the phenomena so well pictured by Dr. Forchheimer, guarding against the possibility of the vasomotor syndrome by proper renal elimination. Attention to proper elimination is of the greatest importance in the management of the cases of pneumonia, looking toward the prevention of cardiac failure; in other words, looking toward the reduction of serious toxic symptoms that arise and have expression more particularly in the phenomena just pointed out. To keep down the amount of food is of the greatest importance in the management of pneumonia patients. Watch carefully the state of the intestinal tract. Tympany is a serious toxic symptom in pneumonia and its increase with defective elimination is a point that I depend on as suggestive of the occurrence of vasomotor failure. This can be prevented very largely. Colitis occurs with the pneumococcus affection, and this colitis is undoubtedly the cause of the development of tympanitis; the colitis plus the toxemia invites an intestinal paresis. Hence to prevent this colitis which gives rise to the tympany, it is well to observe carefully the diet, regulating judiciously the amount and kind of food taken, and washing out the bowels with normal salt solution. Basing treatment on the idea that cardiac symptoms are threatened when renal insufficiency appears, I begin very early the use of caffein; this is perhaps the only remedy I would begin with as a routine measure. In addition I rely on cocain when the conditions become more extreme.

In regard to right-sided dilatation of the heart I agree with Dr. Rochester as to the value of early venesection. One must remember that we must not place too much stress on the physical signs brought out by percussion and auscultation. I am not so much disturbed by the development of murmurs suggestive of dilatation as I am of the appearance of vasomotor phenomena. I am not alarmed when asked to see cases of old valvulitis with mitral regurgitation. When we observe a murmur over the right heart, or a murmur at the apex, there comes into play the safety valve action of the tricuspid; this was pointed out long ago by Guiteras and often bodes much good in these cases.

DR. ALEXANDER LAMBERT, New York: Eight years ago I became dissatisfied with the results of the treatment of pneumonia that I had been following; they were very unsatisfactory and I decided that when a large number of pneumonia cases came into the hospital, as at Bellevue Hospital, it would be well to compare the results of different treatments carried on simultaneously. In my division at Bellevue Hospital (there are four divisions), I gave up the use of alcohol and nitroglycerin and simply used those drugs by which we obtain a rise in blood-pressure. After three months, when each division had had from 125 to 137 patients each, I found that in those cases where alcohol and nitroglycerin has been used, the statistics were 10 per cent. higher in death rates in which the vasodilators had been used than were shown by those in which the drugs that raised the blood-pressure had been used. In other words, judging from about 500 patients affected with pneumonia, the death rate was improved 10 per cent. by camphor, caffein, digitalis and agents which raised the blood-pressure.

Dr. Theodore Potter, Indianapolis: The most remarkable phenomena occurring in lobar pneumonia are at the crisis and, in studying that crisis, it is made plain, as Dr. Forchheimer stated in his paper, that there is great danger to the heart, not from mechanical obstruction but from the toxemia. In dealing with this toxemia there are two chief things to help us; a rational comprehension of elimination in a natural way through the skin, kidneys and bowels, and an unlimited supply of fresh air to the lungs. After all, when these things are compared with drugs directed to the cardiovascular conditions, it seems to me they are far superior. Every one I think who has had to deal with pneumonia cases in an ordinary hospital has felt the great limitations under which he labors in the hospital ward. It is almost impossible in such hospitals to apply the rational fresh-air treatment in lobar pneumonia. Here, there are a large number of patients in the same ward; this is especially true in the large city hospitals. At times I have had to adopt certain expedients. I have taken patients into the delirium tremens room where the windows are kept open; here they could get the fresh-air treatment. But in private practice the problem confronts us, how to apply the fresh air treatment in a rational way. I am sure that everyone who sees such cases in his own practice or in consultation is confronted by it. I have got into the habit lately in teaching medical students of emphasizing the fact that the chief point in the whole matter of carrying out the fresh-air treatment, especially during the winter months it that there should be two rooms in the house for the treatment of such patients; that is practically the solution of the question. Time and again I have seen merely a crack of the window open; that is not real fresh-air treatment. The solution of this problem is in having a place for the patient and a place for the nurse. The nurse should have one room, and the patient another. This is the only way that the fresh-air treatment of these patients can be properly applied.

Dr. Frederick Forchheimer, Cincinnati: In making a diagnosis of congested or over-filled right heart, it is not necessary to prove by percussion, auscultation or inspection that the right heart is enlarged. The diagnosis of this condition can be made perfectly well by simply looking at the patient. It is almost impossible to err in regard to the existence of this form of heart trouble, or the existence of the Romberg-Pässler syndrome. In the Romberg-Pässler syndrome a vasomotor affection we have the addition of a profound anemia and a condition of collapse. In the other condition we find the opposite. We have fulness of the veins, congestion of the face, and all the evidence of dyspnea, an active dyspnea. There can be no mistake regarding the diagnosis, and one need not be so very particular about the direct examination of the right heart. In the treatment of this Romberg-Pässler syndrome, or vasomotor paralysis, I do not believe that digitalis is indicated, and for two reasons. In the first place it does not produce sufficient contraction of the splanchnic vessels to help in relieving the syndrome. In the second place if we increase the heart's activity by increasing the force of the systole, the result will be that the heart will force so much blood into the splanchnic area that it will be more embarrassed than before.

I do not believe we are going to gain much by the use of camphor, musk and other agents in this condition. I believe, however, that in cases of acute myocardial insufficiency either one of these remedies can be used with the greatest good to the patient. As to the question of blood pressure, I believe that Dr. Hoover is correct in what he has stated, but in conditions of splanchnic paralysis the blood-pressure tells the story; it shows that something extraordinary must have happened and this depends entirely on the localization of a mass of blood engorged in the splanchnic area. Those of us who have taken many blood-pressure observations have found that after the second or third day of a pneumonia the pressure is 100 or 102 mm.; that is a low pressure.

I have stated that, according to my belief, tympany is due to a vasomotor paralysis. That is why symptoms of tympany are always to be feared by the clinician.

We have all been using fresh air for a long time; in fact, v. Jürgensen recommended it in 1874 and possibly it was recommended even before that date. I have been using fresh air during the past thirty years in the treatment of pneumonia, and twenty-five years ago I published a paper on the subject. I think that of all the things recommended in the treatment of pneumonia fresh air is the most important. But there is no question regarding carrying out this plan of treatment in the hospitals; I think it can be carried out in the hospital even better than in private practice. All my patients in the hospital are treated by fresh air and simply by using a window tent or by keeping the windows wide open and the results are perfectly satisfactory.

I should like to make a statement in regard to the number of patients who have had this syndrome and whom I have treated. I have had a large number of such patients and I should say, without being mathematically correct, that about 50 per cent. were helped when the treatment was instituted early enough. Recently I saw a patient who had been suffering with this syndrome for twenty-four hours; I succeeded in raising the blood-pressure a little with adrenalin; the injection of caffein did not bring the blood-pressure up. A few hours later a second dose was given. I worked with that patient for some time but he finally died. If this patient had been treated early, and this is a very important part of the treatment, the result might have been different.

THE ACTION OF INTESTINAL ANTISEPTICS ON PEPTIC DIGESTION [*]

ALFRED HEINEBERG, P.D., M.D.
Demonstrator of Therapeutics in Jefferson Medical College; Instructor in Materia Medica in the Philadelphia College of Pharmacy
AND
GEORGE BACHMANN, M.D.
Demonstrator of Physiology in Jefferson Medical College
PHILADELPHIA

It is generally conceded, both from experimental and clinical observation, that fermentation of the contents of the alimentary canal assumes pathologic importance in proportion to the degree of retardation of digestion. To prevent the development of fermentative changes it is customary to administer certain drugs, commonly called intestinal antiseptics, with the end in view of inhibiting the growth of the bacteria responsible for the abnormal condition. If it can be determined that the action of the digestive juices is still further impaired by drugs whose effects on the intestinal bacteria are at best problematical, then their use will be shown to be harmful. The object of this experimental inquiry was to determine, if possible, how far intestinal antiseptics interfere with the action of artificial gastric juice on protein matter.

We present the results obtained merely as a suggestion, for we fully appreciate the inherent difficulty of comparing experiments *in vitro* with processes occurring in the living animal body.

In reviewing the literature we find that Wolberg[1] in 1880 was the first to investigate this subject. He studied the action of various drugs and alkaloidal salts on the digestion of fibrin in a peptic juice made from a glycerin extract of the stomach of the ox. Fubini and Fiori[2] in 1881 determined that potassium iodid disturbed the peptonization of albumin in both artificial digestion and in animals. Extending the method of Wolberg, Dusterhoff[3] experimented with organic and inorganic iron preparations and found that the former produced a greater disturbance of digestion. The bismuth salts, especially the subnitrate, were shown by Israel to affect digestion in no essential way.

[3] Dusterhoff: Diss. Berlin, 1882.

Schütz,[4] employing the polariscopic method of Klikowicz[5] of estimating the amount of peptone after digestion of egg albumin *in vitro,* determined that alcohol in the proportion of 2 per cent. inhibited and in 15 per cent. entirely stopped peptic digestion; corresponding results were obtained with salicylic acid in the strength of 0.006 per cent. and 0.01 per cent. The method of Katz[6] appeals to us as the most scientific and accurate; in a series of experiments on the effect of many drugs on artificial digestion, Katz estimated the peptone as nitrogen by the Kjeldahl process, after precipitation and separation of the undigested albumin. His results are as follows: Morphin hydrochlorid and sulphonal (3.0 to 200 c.c. of fluid) inhibited the action of pepsin on albumin; atropin sulphate, strychnin nitrate, tincture of nux vomica, chloral hydrate, potassium arsenate, tincture of strophanthus and creosote (in small quantity) were without effect; quinin sulphate, bisulphate and hydrochlorid caused an increased formation of peptone.

In our research we have studied the action of ten of the commonly used intestinal antiseptics on the digestion of egg albumin by pepsin. Five series of experiments have been carried out. In one we used the process recommended by the U. S. Pharmacopeia, 1900, for the assay of pepsin; and in the others, a modification of this test for reasons stated below. In the U. S. Pharmacopeia test, 10 gm. of coagulated egg albumin, passed through a No. 40 sieve, are digested with 0.003 gm. of pepsin in 40 c.c. of a 0.3 per cent. solution of hydrochloric acid at a temperature of 52 C. for two and one-half hours. The albumin and artificial gastric juice are agitated by inverting the receptacle once every ten minutes. At the end of the required time, 50 c.c. of cold water are added and the whole poured into a sedimenting tube and allowed to stand for one-half hour; then the quantity of undigested albumin is read off in cubic centimeters or fractions thereof. The amount of undigested albumin in the tube should not be more than 1 c.c. with pepsin of standard strength. We had some difficulty in obtaining pepsin which would conform to this test; many of the pepsins purchased in the open market were below the required standard.

The quantity of each drug to be employed in the tests was determined as follows: According to Atwater, an adult ingests about 120 gm. of proteid in twenty-four hours; this divided into three parts would be 40 gm. for the average meal. The percentage of proteid in egg albumin is about 12.5 per cent. or one-eighth. The 40 gm. of proteid, estimated as moist egg albumin, is equivalent to 320 gm.; hence the 10 gm. of albumin used in the test represent approximately one-thirtieth of the proteid ingested at each meal. On this basis we added one-thirtieth of the average dose of each drug to each test.

In the first series, in order to obtain one-thirtieth of the dose, we mixed with the average dose of the drug enough sodium chlorid to make thirty grains and used one grain of the resulting powder to each test.

Our results were shown in Table 1.

It will be seen in this series that peptic digestion was much disturbed, the amount of sediment being in every case more than in the control. Moreover, it will be observed, the state of division of the sediment in the control is much finer than in the tubes containing the antiseptics, indicating a farther advance in the process of digestion.

It seemed to us that the results obtained by subjecting the pepsin in the above tests to the temperature of 52 C. instead of about 40 C., at which digestion proceeds in the stomach, could not be compared with what occurs during gastric digestion. Of course, as already intimated, we are well aware that it is not justifiable to draw any parallel between experiments *in vitro* and similar processes taking place *in vivo.* Nevertheless we wished to imitate as closely as possible the conditions present during gastric digestion. Accordingly we modified the U. S. Pharmacopeia test as follows:

TABLE 1.—SERIES 1, PROCESS U. S. P. 1900

Albumin disintegrated by being passed through a No. 40 brass sieve; digested for two and one-half hours.

	Sediment. c.c.	State of Division.
Control	13	Very fine.
Acid, benzoic	23	Fine.
Acid, boric	23	Moderately fine.
Acid, salicylic	25	Coarse.
Beta-naphthol	25	Coarse.
Creosote	26	Coarse.
Phenol	24	Coarse.
Resorcinol	22	Moderately fine.
Sodium phenolsulphon.	24	Moderately fine.
Sodium sulphite	25	Coarse.
Thymol	24	Moderately fine.

Instead of the 0.3 per cent. solution of hydrochloric acid we employed a 0.25 per cent. solution, which more closely corresponds to the percentage found in gastric juice; the amount of pepsin remained the same, as did also the quantity of egg albumin used in the previous test; the quantity of hydrochloric acid used was 50 c.c. Thinking that perhaps the sodium chlorid with which the drugs were diluted had some active influence on the test, we decided to eliminate that factor by dissolving the drugs in such a quantity of water that 5 c.c. of the solution would represent one-thirtieth of the average dose. The addition of the 5 c.c. of the drug solution would naturally lower the strength of the hydrochloric acid solution; we, therefore, added sufficient hydrochloric acid to compensate for that effect.

TABLE 2.—SERIES 2, PROCESS, MODIFIED U. S. P.

Albumin disintegrated by being passed through bolting cloth.

	Sediment. c.c.	State of Division.
Control	5.5	Moderately fine.
Acid, benzoic	8	Fine.
Acid, boric	6.5	Moderately fine.
Acid, salicylic	8	Moderately fine.
Beta-naphthol	7.5	Moderately fine.
Creosote	6.5	Coarse.
Phenol	6.5	Moderately fine.
Resorcinol	6	Moderately fine.
Sodium phenolsulphonate	6	Moderately fine.
Sodium sulphite	12.5	Coarse.
Thymol	7	Moderately fine.

TABLE 3.—SERIES 3. PROCESS AS IN NO. 2, EXCEPT AS FOLLOWS:

The albumin was disintegrated by being passed through a No. 20 horsehair sieve.

	Sediment. c.c.	State of Division.
Control	13	Fine.
Acid, benzoic	14	Moderately fine.
Acid, boric	13	Moderately fine.
Acid, salicylic	16	Moderately fine.
Beta-naphthol	16.5	Moderately fine.
Creosote	15	Moderately fine.
Phenol	14	Moderately fine.
Resorcinol	13.5	Moderately fine.
Sodium phenolsulphonate	14	Moderately fine.
Sodium sulphite	18.5	Coarse.
Thymol	18	Moderately fine.

The temperature at which the albumin was digested was 40 C. and digestion was allowed to proceed for four hours, the containers being agitated by inverting them once every ten minutes. At the expiration of the time the contents of the receptacles were poured into the sedimenting tubes and enough cold distilled water added to make 100 c.c. After sedimenting for one hour the cubic centimeters of undigested albumin were read off.

---

[4] Schütz: Prag. med. Wchnschr., 1885, xx, 193.
[5] Virchow's Arch. f. path. Anat., 1885, cii, 360.
[6] Katz: Wien. med. Bl., 1889, xii, 19, 436, 453.

In this series the antiseptics have not interfered as much with the digestion of the albumin as in Series 1, although it is quite evident that they have had a retarding influence.

Comparison of Series 2 and 3 will show that the results correspond fairly well. The difference in the amount of albumin digested is probably due to the fact that a different brand of pepsin was used in each and the particles of albumin were much larger when passed through a No. 20 sieve than through bolting cloth, the coarser particles being more resistant to the action of the artificial gastric juice. In an average of the three series it will be noted that sodium sulphite was the most powerful in retarding digestion and that boric acid and resorcinol were the least active.

We do not believe that by the use of the U. S. Pharmacopeia process and modifications of it thus far employed in this study one can arrive at accurate conclusions either as to the digestive power of pepsin or to the effect which other substances may have on peptic digestion, even *in vitro.*

We, therefore, thought it advisable to resort to a different and more accurate method. This consisted in estimating the amount of peptone and allied products formed at the end of digestion by determining their nitrogen content according to the Kjeldahl method as recommended by Katz.[6]

The digestion of 10 gm. of coagulated egg albumin was performed as in Series 2. At the end of digestion the undigested albumin was precipitated by the addition of sodium chlorid to saturation to each bottle, followed by a few drops of acetic acid saturated with sodium chlorid. The solution of peptones was separated by filtration and its nitrogen determined as beforesaid by the Kjeldahl process.

The average of two series of experiments gave the following results shown in Table 4:

TABLE 4.—NITROGEN YIELDED BY PEPTONES *

	Quantity. Gm.	%
Control	0.01197	100
Acid, benzoic	0.0077	64
Acid, boric	0.00962	80
Acid, salicylic	0.00857	71
Beta-naphthol	0.00822	68
Creosote	0.00875	73
Phenol	0.0084	70
Sodium sulphite	0.00875	73
Thymol	0.00945	78

* Estimating control at 100 per cent.

CONCLUSIONS

1. Intestinal antiseptics interfere with peptic digestion *in vitro.*
2. Beta-naphthol, salicylic acid, sodium sulphite and thymol are the most active in retarding digestion.
3. Boric acid and resorcinol are the least active.
4. The uniformity in the results of our experiments would seem to warrant the inference that intestinal antiseptics interfere with digestion in the stomach and probably in the intestine.

A Model City.—Our national capital, the city of Washington, should be a model sanitary city, free from insanitary tenements and workshops, air pollution, water pollution, food pollution, etc., with a rate of death and a rate of illness so low as to arouse the attention of the world.

THE PARALYTIC COMPLICATIONS OF HERPES ZOSTER OF THE CEPHALIC EXTREMITY

A PRELIMINARY REPORT ON THE HERPETIC INFLAMMATIONS OF THE GENICULATE, GLOSSOPHARYNGEAL, VAGUS AND ACOUSTIC GANGLIA *

J. RAMSAY HUNT, M.D.
NEW YORK

Idiopathic or true herpes zoster is an acute infectious disease characterized by general symptoms; fever, headache and great prostration and a focal manifestation; an eruption of herpes zoster on the skin and mucous membranes.

The characteristic pathologic changes are found in the posterior spinal ganglia and in the Gasserian ganglion *(posterior poliomyelitis).* These structures are derivatives of the so-called neural ridge, and the ganglion cells having this origin belong to the so-called unipolar or spinal type. The geniculate ganglion, the ganglia of the glossopharyngeal and vagus nerves, as well as the auditory ganglia (the *ganglion* of *Scarpa* and the *ganglion spirale*) also take their origin from the neural ridge, and as such must be brought within the realm of the specific ganglionic inflammation of herpes zoster.

The affected ganglion is the seat of an hemorrhagic inflammation which gives rise to pains (herpetic neuralgia), objective sensory disturbances and an eruption of herpes zoster in the zone corresponding to the affected ganglion. Milder inflammatory changes may also be present in the ganglion above and below the chief or eruptive focus. I have studied the motor complications of this affection, and more especially the cranial nerve palsies and auditory symptoms which occur in the cephalic zona.

I have collected, including my present observations, reports of 158 cases of paralyses of various kinds in herpes zoster, a complete analysis of which will be published later. They are distributed as follows:

Motor oculi, 18 cases.
Trochlearis, 1 case.
Abducens, 5 cases.

All these ocular palsies were associated with herpes frontalis or herpes facialis.

Brachial palsies, 12 cases. Eight of these were of the upper-arm types and four were mixed, upper- and lower-arm types. These arm palsies all occurred in herpes zoster of the upper extremity.

Abdominal palsies, 2 cases. These were associated with herpes zoster of the trunk.

Facial palsies, 80 cases. In all of these, the eruption was confined to the cephalic extremity of the body as follows:

Herpes occipito-collaris, 43 cases.
Herpes facialis, 14 cases.
Herpes oticus, 19 cases.
Herpes facialis and herpes occipito-collaris combined, 1 case.
Herpes oticus and herpes occipito-collaris combined, 3 cases.

Auditory nerve complications were present in 30 of these cases. They varied in character from a simple diminution of hearing to a severe form of Ménière's syndrome.

The occurrence of herpetic inflammations in the glossopharyngeal and vagus ganglia is worthy of emphasis for the relation which they bear to the herpes pharyngis, herpes laryngis and herpes oticus.

---

* Read in the Section on Nervous and Mental Diseases of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

In some of these cases pneumogastric symptoms have been observed; such as bradycardia, hiccoughing, nausea and vomiting.

I, therefore, attribute to the zona of the cephalic extremity a special importance, because of the occurrence of facial palsy, deafness, symptoms of Ménière's syndrome and vagus symptoms.

These cranial nerve complications do not occur except in herpes zoster of the face, ear, pharynx, larynx and the head and neck. Therefore, these various clinical types should be regarded as constituting a definite clinical entity. I consider the zoster zones for the geniculate, glossopharyngeal, and vagus ganglia as capable of being differentiated (herpes zoster oticus, pharyngis et laryngis).

The clinical types are as follows: Herpes facialis, herpes oticus, herpes pharyngis, herpes laryngis, herpes occipito-collaris; with facial paralysis and auditory symptoms, alone or in combination.

The facial palsy in 50 cases occurred without auditory symptoms. In 30 cases of the total number (80) both facial and auditory symptoms were present. The acoustic symptoms may also occur without the facial paralysis. In some cases the auditory ganglia are alone the seat of the herpetic inflammation, giving rise to tinnitus aurium and deafness, and in some cases symptoms of Ménière's disease.

Rarely vagus symptoms may be present, hiccoughing, bradycardia and vomiting. The underlying pathologic condition in all of these types is a herpetic inflammation of cranial nerve ganglia.

112 West Fifty-fifth Street.

ABSTRACT OF DISCUSSION

DR. JAMES ALLEN PATTERSON, Colorado Springs, Colo.: The rarity of paralytic lesions is noticeable in the literature of ophthalmic herpes, and as I had a case last winter in which there was distinct paralysis of the external ocular muscles as well as of the pupil, I was particularly anxious to hear this paper. I want to remark in particular the infrequency of paralytic phenomena in ophthalmic herpes as seen by oculists.

DR. HOWELL T. PERSHING, Denver: Does Dr. Hunt regard the view that herpes follows specific inflammation as being confirmed, and does one attack of herpes protect the individual from a further attack?

DR. J. R. HUNT, New York: I regard the true herpes zoster as a specific infectious disease. It is a disease in which the lesion is situated in the ganglion, although one must also recognize neuritic herpes and zosteroid condition of the skin which resembles it.

Fatal Effects of Lowered Air Pressure Not Due to Lack of Oxygen.—In rarefied atmospheres such as are encountered at high elevations, it is not the scarcity of oxygen which produces the weakness and depression and the other symptoms which usually accompany mountain sickness, but rather the disturbance of the circulation in the lungs due to the purely mechanical effects of a lower barometeric pressure. A. Rosendahl (*Ztschr. f. Biol.*, 1909, lii, 16), has produced in rats and rabbits, by exposure to an atmosphere which contained an excess of oxygen, but which was reduced to a low barometric pressure artificially, symptoms analogous to those seen in mountain sickness in these animals. The animals soon recovered when transferred to an atmosphere of ordinary pressure which contained less than the ordinary quantity of oxygen and an excess of nitrogen. It was further found that rats and rabbits became dyspneic in an atmosphere containing mostly oxygen, if the air pressure was only slightly lowered. An increase of pressure above the normal was well endured in atmospheres of normal consistency and in those which contained a high percentage of nitrogen.

LICHEN PLANUS

A CONSIDERATION OF ITS ETIOLOGY AS ILLUSTRATED BY AN ACUTE CASE *

DOUGLASS W. MONTGOMERY, M.D.
AND
HARRY E. ALDERSON, M.D.
SAN FRANCISCO

We believe lichen planus to be a distinct disease, and we also believe it to be a constitutional disease with manifestations on the skin and mucous membranes.

Lichen planus almost always occurs in its chronic forms, and as such its constitutional symptoms are frequently so slight as to escape detection. In the acute cases, however, the general constitutional symptoms become salient and form an important part of the clinical picture, of which the following is an example:

HISTORY OF CASE

Patient.—An obese, pulpy-looking Mexican woman, aged 40, and engaged in general housework, entered the University of California Hospital, July 8, 1908, with a very itchy tormenting eruption. She said that before its appearance she had worked very hard for some time and that for several months she had not menstruated.

History.—Previous to this her menstruation had been normal, and she had enjoyed good health. Her present trouble came on about the middle of June, 1908, that is, about three weeks before entering the hospital. She said she suddenly began to feel very sick, nauseated, had feverish sensations alternating with chills, most marked at night, indefinite shifting pains, and great prostration. Coincidently with these symptoms there suddenly appeared all over the body a rash, which she said was like the present eruption, but much more itchy.

Examination.—When the patient entered the hospital she had a lichen planus eruption almost universal in distribution, but gradually becoming less profuse along the extremities, and entirely sparing the hands and feet. The buttocks were also free from eruption, and there was a free strip down the inner side of both upper extremities. The scalp was studded with papules and the rash on the face was confluent, the lower eyelids were swollen, and the conjunctivæ were so inflamed as almost to evert the lids. Typical papules could be best seen on the forearms, where they were scattered between the large rounded ones. They were small, angular, yellowish red, firm, flat-topped, waxy, glistening and in many instances covered with a thin, tightly adherent scale. A few were umbilicated. All of the papules on the face, however, and most of those on other parts of the skin, were large, rounded, prominent, firm bodies resembling in appearance the lesions in syphilis or leprosy, but differing in being intensely pruritic. These papules were indeed so firm as to give the impression of little tumors set in the skin, and their rounded prominent shape was so pronounced as to deserve the designation "obtusus," although as Brocq has remarked, this adjective is applied to another form of lichen planus.[1] At first glance, indeed, it looked as if the patient were afflicted with leprosy, but this resemblance was soon seen to be fallacious, as on minuter examination the differences were seen to be more marked than the similarities. To clinch the matter, however, the juice from some of the tubercles was stained for lepra bacilli, and none was found. As for syphilis, the eruption was altogether too slow in its evolution and involution, and too thickly strewn on the face, and besides it was intensely itchy. There was no history of syphilis, no mucous patches, and the superficial lymphatic nodules were not enlarged, as they would be in early constitutional syphilis. The patient's tongue was heavily coated, the breath was foul, the throat was sore, and there were whitish, sodden-looking patches on the tonsils, which were thought to be exudate from the intensely inflamed tonsils, and were certainly not characteristic of either syphilis or lichen. No lichen patches were found on any of the mucous membranes, in this respect following the rule when the eruption is acute and generalized.[2] The gastrointestinal tract was very sluggish. The liver was slightly enlarged, but not tender. There was no demonstrable enlargement of the spleen or of the lymphatic nodules. The right lobe of the thyroid was slightly enlarged. Dr. William G. Moore found no abnormality in the vagina or pelvis. The temperature and pulse were normal in the morning, but toward evening the temperature ran up to 38. The blood examination showed:

---

* Read in the Section on Dermatology of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

[1] Brocq, L.: Dermatologie pratique, ii, 198.

Hemoglobin	85
Erythrocytes	3,808,000
Leucocytes	7,000
Polynuclears	75
Large mononuclears	8
Small mononuclears	13
Eosinophiles	4

An examination made one month later showed practically the same proportions. The urine was dark yellow, turbid, and its specific gravity was 1,021. It was acid, contained no sugar, and showed a trace of albumen. There was an occasional hyaline and granular cast, a few red blood corpuscles, very many squamous epithelial cells, and many white cells.

Treatment and Course of Disease.—A soothing line of treatment was adopted, and she was given:

℞		gm. or c.c.	
Liquoris picis carbonis (B. P.)		2	m.xxx
Liquoris plumbi subacetatis		12	fl.ʒiii
Olei olivæ			
Liquoris calcis	āā	60	fl.℥ii

M. et sig.: Use externally.

℞		gm. or c.c.	
Magnesii carbonatis			
Bismuthi subnitratis	āā	20	ʒv
Tincturæ rhei		90	fl.℥iii
Aquæ menthæ piperitæ	ad	240	fl.℥viii

M. et sig.: A dessert spoonful after eating, three times daily.

In the first forty-eight hours she was given milk alone, and afterward other foods were slowly added. The general condition and skin slowly improved. At times, however, she had acute sore throat, headache, fleeting pains in the joints, malaise, violent conjunctivitis, erythema of the eyelids and face, and a marked extension of the papular eruption, resembling in these respects the case of Nicholas and Favre.[3] The temperature ran along between 36.2 and 37.4 until August 10, when it jumped up as will be noted later.

About July 31 her eyelids became swollen and very painful, her throat again became sore, and she complained greatly of shifting pains in the joints. The trouble in the eyes was relieved by boracic acid cold compresses, and drops of a 5 per cent. argyrol solution, and the pains in the joints were controlled by five-grain doses of aspirin given every three hours, and at the same time the other symptoms were relieved. This control of the symptoms by one of the salicylates, aspirin, is very interesting and will be referred to later. On Aug. 10, 1908, on Dr. Howard Morrow's suggestion, atoxyl 0.10 was given intravenously. The patient was rather languid all through the next day, and complained of general soreness in the lesions of the skin, and of frontal headache. On the following day there was decided malaise, and the general pains were rather severe, being most noticeable between the scapulæ. During these two days the temperature gradually ascended till it reached 38.5. On the third day after the atoxyl injection, the temperature dropped to normal, she felt quite well again, and there seemed to be some improvement in the skin. These injections were resumed on August 15, and from August 15 to August 24 she was given an injection of 0.15 atoxyl every second day, without producing any reaction. Although the atoxyl did not give any reaction yet the patient steadily continued to grow worse and the itchiness, especially of the eyelids, increased. The patient was now given:

℞		gm. or c.c.	
Hydrargyri chloridi corrosivi		0.06	gr.i
Syrupi sennæ			
Aquæ	āā	60	fl.℥ii

M. Sig.: A teaspoonful in a little water after food, t. i. d.

Under this mixture the patient slowly and steadily improved for one month when she complained of sore throat and increased itchiness of the face. The dose of corrosive sublimate was then raised from 0.002 to 0.005 and 0.6 of iodid of potash was added to the prescription.[4] The improvement that had set in on giving the corrosive sublimate continued. and no special effect was noted as following the addition of iodid of potash. This treatment was continued for about one month when papules over the glabella, above the eyebrows, and on the upper arms became markedly hyperkeratotic, each papule being crowned by a gray, hard, dry, tightly adherent, coruscated crust. At the same time she complained of sore throat and increased itchiness of the face. For this hyperkeratosis she was given an 8 per cent. ointment of salicylic acid. The active lesions steadily disappeared, and the hyperkeratosis improved, but now the subjective symptom of universal formication became very pronounced, and it was thought that arsenic might be beneficial. She was then given 0.12 doses of Fowler's solution three times a day for a week. The whole condition became suddenly worse, and she got a herpes labialis. She was put back on corrosive sublimate and iodid of potash.

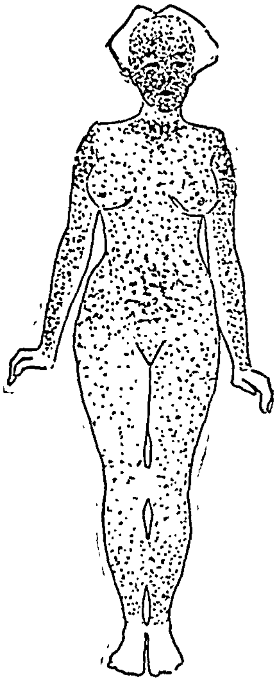

Fig. 1.

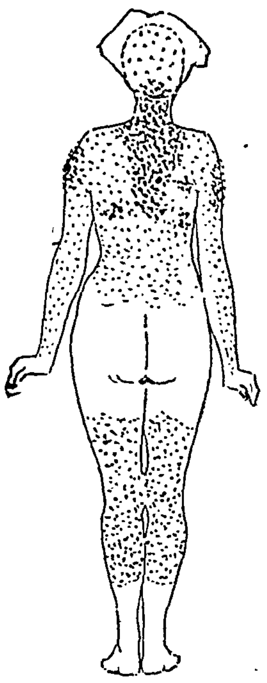

Fig. 2.

Figs. 1 and 2.—Distribution of lesions. Note free areas; feet, hands, inner surfaces of upper limbs, buttocks and upper part of thighs.

By Feb. 3, 1909, a pea-sized intensely itchy hypertrophic scar had developed in a biopsy wound. On Feb. 24, 1909, the iodid of potash was omitted from her prescription because of a profuse mucous discharge from the nose. The pigmented lesions were at this time slowly fading. The patient called again on March 22, because of a few acute very itchy lesions over the supraorbital ridges, on the chin, upper lips, cheeks and over the elbow tips. Her tongue was heavily coated, breath foul, gums tender, teeth "on edge," and she had diarrhea. She was evidently suffering from hydrargyrism, and the alimentary disturbance consequent on this was accentuated by her occupation as cook in a Mexican restaurant, and eating between meals. This lichen outburst was particularly interesting because it occurred while deeply under the influence of mercury. We concluded in fact that the mercury and the errors in diet, by causing irritation of the alimentary tract, were the cause of this outbreak. Consequently the mercury was dropped, and a mixture composed of carbonate of magnesia, subnitrate of bismuth and tincture of rhubarb was prescribed, under which the acute symptoms subsided.

---

[2] Radcliffe-Crocker: Brit. Jour. Dermat., February, 1908, p. 47.

[3] Nicholas and Favre: Ann. de dermat. et de syph., July 1906, page 701. In a case reported by Dr. Howard Fox also (Jour. Cut. Dis., May 1908, p. 237) at the beginning of each attack of lichen ruber the patient generally felt weak and nauseated.

[4] This was in accordance with the recommendation given by Hardaway and Grindon (Cutaneous Therapeutics, p. 169).

Another biopsy was made at this visit of a lesion that had reached the pigmented depressed scarlike stage. This wound was dressed with collodion and cotton, and interesting to relate, the patient returned four days later with a beautiful bullous eruption surrounding the collodion dressing. We think it probable that the occurrence of the bullæ was a manifestation of the peculiar kind of irritability of the skin in these cases, and was of the same nature as the intercellular and intracellular edema and the subepithelial cleft so often observed in this disease.

It was about this time that, in conversation, Dr. H. R. Oliver mentioned that, in a case diagnosed as lichen planus by two well-known dermatologists, a Wassermann reaction positive for syphilis had been found. Dr. Oliver kindly consented to test our patient in the same way, and found her also positive for syphilis. This result caused us to review our facts carefully lest, in view of the success achieved with mercury and iodid of potash and the failure of arsenic, the presence of a few equivocal histologic features and also the difficulty often experienced in differentiating the eruption of lichen planus from some of the papular eruptions of syphilis, some should conclude that we have here to do with lues and not at all with lichen planus. That this patient may have acquired syphilis may be true. When her throat was intensely inflamed, in the early stages of her trouble, she had a white coating on her tonsils, and at one time she had a white patch on her lip. The tonsillar coating, however, was not at all characteristic of syphilis, and the lesion on the lip looked more like a cigarette burn or a herpes simplex than a mucous patch. Nevertheless scrapings from it were carefully searched for spirochetes, but none was found. Also it was noticed when making the atoxyl injections, that her veins were hard and brittle, and microscopically the arteries of the skin were thick-walled and had sleeve-like infiltrations which may have been due in part, at least, to syphilis. As for the eruption, however, that was another story. Although many of the individual papules resembled the papules of syphilis, yet the stormy intensely itchy nature of the attacks, associated with acute conjunctivitis and sore throat, and the long endurance of the eruption and uniform character of the lesions gave a picture entirely different from anything observed in syphilis. It is interesting also to note here that although the patient improved under bichlorid of mercury, yet as soon as the mercury began to salivate and so to irritate the alimentary canal new lichen papules began to appear. Microscopically also, as will be stated later, the infiltration of mononuclear cells resembling lymphocytes into the upper corium sharply circumscribed below, together with degeneration and absorption of collagen and elastin, and the subepidermal cleavage were changes just such as we would expect to find in lichen planus, and were not those of syphilis.[5]

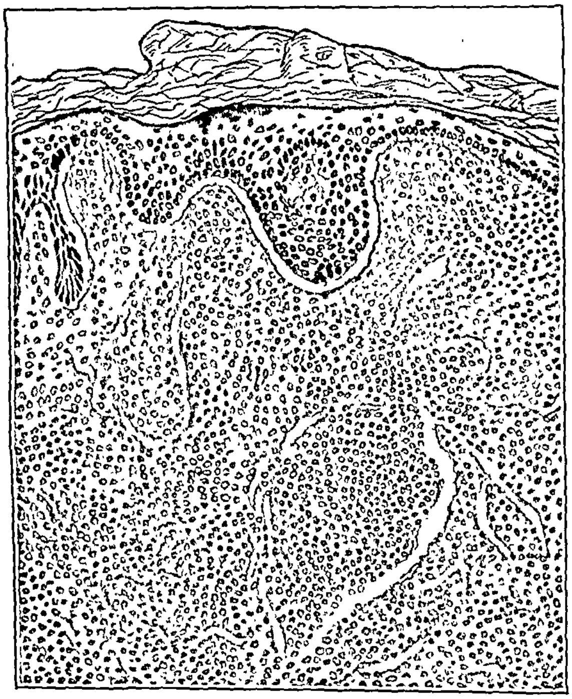

Fig. 3.—Microscopic view of cross-section of early lesion; this and the following illustrations are from drawings by Dr. A. W. Lee of the Medical Department of the University of California.

HISTOPATHOLOGY

EARLY LESION

About three weeks after the onset of the disease a small unscratched papule was removed from the right forearm under ethyl chlorid anesthesia locally. It was fixed in Müller's solution and formaldehyd, equal parts, hardened in alcohol, mounted in celloidin and stained in various ways. This lesion in many details corresponded with the findings of various investigators of lichen planus, but in some of its features it was somewhat atypical. Briefly, the following were to be observed:

Epidermis.—Stratum corneum: Hyperkeratosis with layers loosely connected. In places horny plugs were formed.

Stratum Lucidum: This was not demonstrable.

Stratum Granulosum: This was deficient, consisting in the main of but one or two layers of cells, but occasionally there was seen a small patch three to four cells deep. The keratohyalin granules were very deficient, and occasionally a clear nuclear space was seen surrounded by a faint zone of protoplasm. The nuclei varied decidedly in staining capacity, some being strongly basophilic and others only slightly so. This stratum had the appearance of being greatly stretched longitudinally.

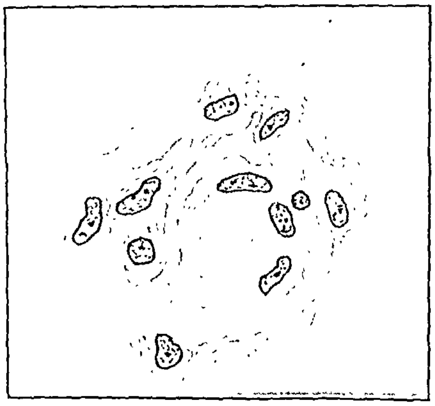

Fig. 4.—Giant cell, early lesion.

Stratum Spinosum: This varied in thickness, averaging four to ten layers. Toward one end of some of the sections, it was very thin and stretched longitudinally. Here also the rete pegs were flattened out. Toward the other end, there was hypertrophy and marked acanthosis. In places just over the papillæ, this stratum was very thin. In the main, the rete pegs were rather widely separated. There was intracellular and intercellular edema. Many of the nuclei were surrounded by a clear zone and occasionally there was seen nothing but a clear space surrounded by a faint zone of protoplasm with well-marked prickles. The prickles persisted throughout, although in places they appeared to be greatly stretched. The nuclei varied greatly in staining capacity. In the lower part of this stratum occasionally the intercellular edema was so great as to suggest commencing vesiculation. There were wandering cells in these intercellular spaces showing ameboid forms, adapting themselves to the tortuosity of the channels.

Stratum Germinativum: This presented two to four layers of cells in which the pigment was deep in color. Over the densest part of the deeper lesion and also where the edema was greatest, the pigment was absent[6].

---

[5] Ehrman and Fick and also G. B. Dalla Favera (Monatsh. f. prakt. Dermat., April 1, 1909) have observed the absorption of elastic tissue in this disease.

[6] Ehrman and Fick (Histopathologie der Haut) note also this absence of pigment.

There was a thin clear line of cleavage between the basal layer and corium, which was bridged over here and there by irregular fibrils, basophilic in reaction.

Corium.—The papillæ, over the lesion, were greatly widened, but elsewhere some could be seen, narrowed and extending almost to the stratum granulosum. There was a dense cellular mass, well circumscribed below and extending up to the epidermis, from which it was separated in places by a narrow zone of basophilic, finely granular collagen, or by the line of cleavage already mentioned. The essential lesion was in the upper corium. At the periphery of this lesion, the cell mass sent out prolongations in thin zones; following the blood vessels a short distance. This cellular mass consisted of several types of infiltrating cells, which will be described in order.

1. The predominating type was mononuclear, round or oval, and as a rule, slightly larger than a red blood cell, but occasionally it was considerably larger. It resembled greatly a mononuclear leucocyte, and frequently could be seen in the lumen of a blood vessel. This type was often observed, assuming ameboid forms, and also it frequently presented appearances strongly suggestive of amitosis. The nucleus was vesicular and faintly basophilic, in some instances, barely staining at all. Seldom could the protoplasm be seen, but sometimes it was represented by a narrow zone slightly basophilic. At times this zone was acidophilic. Occasionally the nucleus was placed eccentrically and the protoplasm was increased. Sometimes the cell body showed prolongations which apparently fused with the adjacent cells.

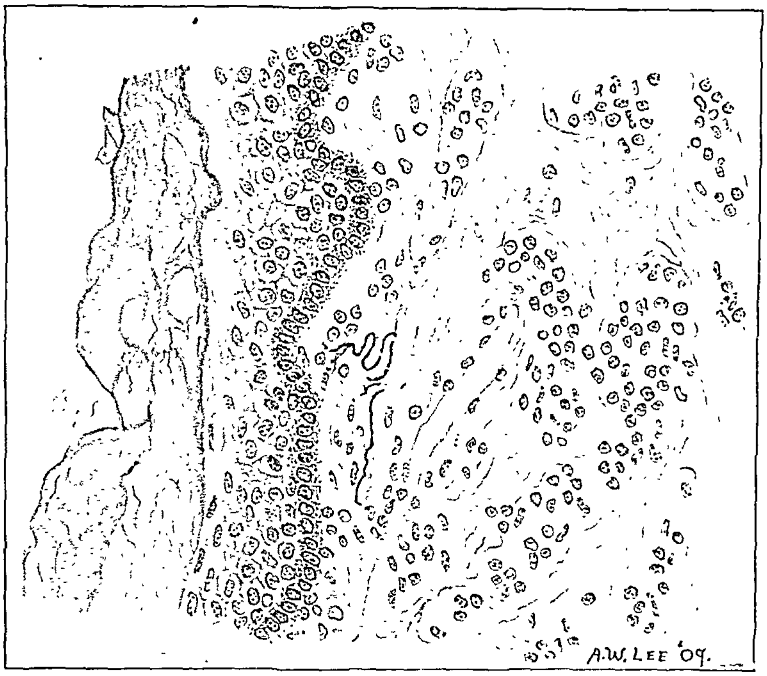

Fig. 5.—Microscopic view of cross-section of late lesion.

2. Furthermore there were smaller round cells with small, rather deeply staining nuclei, which were usually placed towards the periphery of the cell. There were no chromatin bodies in evidence, the nucleus presenting a homogeneous appearance. The protoplasm was usually acidophilic and occasionally very strongly so. This type also would be seen in some of the vessels. It often resembled morphologically the small tissue plasma cell. Occasionally two nuclei were seen, one at either pole of the cell.

3. Giant cells were seen with deeply staining nuclei, resembling in form those of connective tissue. These nuclei varied from three to fifteen or more in number in each cell. They were arranged peripherally toward one pole, and as a rule, within a narrow zone of the colloid protoplasm, but occasionally they were grouped in a bipolar manner. Two or three typical giant cells, and numerous incomplete forms were seen in each section.

4. There had evidently been some proliferation of connective tissue cells, for their nuclei were seen in increased numbers. They presented evidence of degeneration in that they were often very pale and often very deeply stained. Their protoplasm was usually basophilic, and corresponded in appearance with that seen in the giant cells.

5. Polymorphonuclear leucocytes were seen fairly often in small groups throughout the lesion, and also in the vessels.

The collagen was very edematous, and showed irregular areas of degeneration. Where the cellular mass was thickest, and particularly along a narrow zone directly beneath the basal layer, the collagen was represented by a degenerated homogeneous, basophilic, finely granular substance. Broken up blocks of basophilic collagen, in transverse section, could be seen here and there. Deeper in the lesion, opaque masses of basophilic collagen could be seen, resembling the degeneration seen in sarcoma. This type existed below this region along with large broken-up masses. This extensive degeneration of the connective tissue was a very interesting feature. The narrow zone of finely granular basophilic collagen, immediately beneath the epidermis, taken in connection with the cleft which occurred here, represented a line of lessened resistance. Bridging across the cleft at frequent intervals were tiny basophilic strands. These bridges were absent for some distance in places.

The elastic fibers had all degenerated along the "zone" above referred to, and only rarely could a few tiny fibrils be seen in a papilla. These fibers were all broken and in places absent, where the cellular mass was most dense and where the collagen had undergone marked degeneration. For the most part the remaining elastic fibers stained deeply, but occasionally they appeared very faintly. They seemed to terminate abruptly about three cell-breadths from the basal layer, at the border of the narrow granular zone above mentioned.

The blood vessels were usually dilated and in their lumina could be seen many red blood cells and mononuclear leucocytes, with occasional polymorphonuclears. The papillary vessels right up to the summits of the papillæ were dilated and full. They all showed thickened walls and greatly swollen endothelium, and were all surrounded by the infiltration and proliferating cells already described. Often the perivascular infiltration was very dense.

The coil glands showed some increase in nuclei, which were deeply basophilic. Usually the lumen was not apparent, but occasionally it could be seen dilated. Portions of their ducts showed no dilatation.

LATE LESION

Five months after the onset of the disease, a pigmented atrophic lesion was removed from the arm, under ethyl chlorid anesthesia locally, fixed and hardened in alcohol, mounted in celloidin and stained in various ways.

The following was to be observed:

The stratum corneum showed hyperkeratosis, and the stratum lucidum was well defined in some sections. The stratum granulosum was deficient, consisting usually of from one to three rows, but occasionally in a small area showing an increase of four to six cells. The entire epidermis was more nearly normal and did not show edema. The rete pegs were still somewhat flattened, and the stratum spinosum was not quite as thick as the normal. Occasionally a little pigment was seen in the stratum spinosum, but pigment in the main was limited to the two or three rows of cells constituting the stratum germinativum, where it was abundant and not absent at any point.

In the corium it could be seen that the edema had subsided, the infiltration had become dispersed in streaks and small foci, and there had been some regeneration of collagen. The infiltration extended in streaks off into the periphery, following the vessels, follicles and ducts. These cells were also grouped into small masses, surrounded by collagen fibers, and situated principally in the upper corium. This infiltration now consisted very largely of typical plasma cells, and many small round cells. Proliferated connective tissue nuclei were present in increased numbers.

There was no line of cleavage at the epidermis border, and the collagen throughout had to a great extent regenerated. The papillæ were still widened and flattened in places.

The elastic fibers showed the same degeneration seen in the early lesion. Deep in the corium some large normally staining fibers were present. There were also some few detached fibers in the papillæ. Elsewhere they were represented by a homogeneous, somewhat granular substance, which took the acid dye feebly.

The collagen, as well as the elastic tissue, was absent in the infiltrated foci.

The blood vessels were not dilated, and were not much in evidence. They showed thickened walls, swollen endothelium, and occasionally could be seen with complete obliteration of their lumen.

The coil glands showed no special abnormality. Their ducts could be occasionally observed slightly dilated.

Very few now believe in the infectious nature of lichen planus; even in those rare instances in which the disease occurs in several members of the same family the malady is attributed to some other cause, such as predisposition.[8] Many observers think the disease of nervous origin, because it occurs in nervous individuals, and because the eruption frequently appears in streaks, seemingly following along nerve tracts. This streaking, however, may be due to another cause. In fact there are many features of lichen pointing directly to its being a general disease with the eruption as one of its symptoms, and the acute cases are the ones that throw most light on this view, as the symptoms are more accentuated. In the first place the skin eruption of lichen may occur on any part of the cutaneous surface, not infrequently in the same patient either at the same time or at different times in widely separated localities. Furthermore, the eruption of lichen often appears on the mucous membranes as well as on the skin, or it may even occur on the mucous membranes alone.[9]

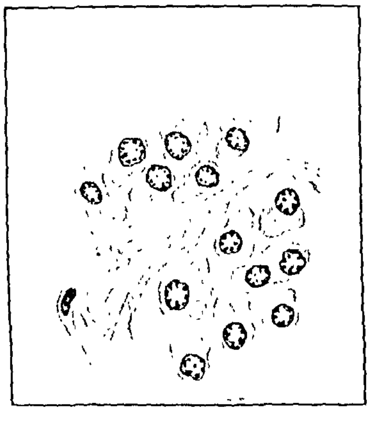

Fig. 6.—Plasma cells, late lesion.

As another evidence of the implication of the whole body in the disease process there is now the well-authenticated fact that the eruption is apt to break out on the site of any unusual irritation. That is to say, the whole skin in lichen subjects is in a state of irritability, and reacts in producing lichen eruption when the right kind of irritation supervenes. This applies probably to the entire mucous membranes as well as to the skin. In this connection we may consider the peculiar susceptibility of lichen subjects to pneumonia as noted by Schütz. Furthermore, he enumerates a great number of changes in the blood circulatory apparatus as being coincident with lichen planus and mentions that Lereddc found overfilling of the blood vessels of the cutis in making a microscopic examination of the sound skin in a lichen patient.[10] The nervous system also often shows a high state of irritability, and it is a frequent observation that these patients are nervous, high-strung and sleepless. It is difficult to imagine anything but a toxin producing these results. The sudden stormy nature of the attacks in the acute cases also looks like the work of a toxin, acting much in the same way as the ferments producing the urticarias. We can imagine such a toxin only as flowing in the blood stream. This is a conclusion also reached by Fordyce.[11] Turning now to the microscopic anatomy of the lichen papule, we find that the earliest lesions are dilatation of the small blood vessels, the outpouring of serum into the affected tissues, and an abnormally stimulated proliferation of these tissues. If this hypothetical toxin is in the blood it will show its greatest effects in that part of an organ where the supply of blood is richest. This is just what we do find in the skin, where the most decided lesions are found in the papillary body, which, as the nourisher of the overlying epithelial layers, is particularly full of blood.[12] The most likely place for the production of this toxin is, of course, the alimentary canal, supplied, as it is, with the complicated ferments of the human being himself, and also with countless numbers of ferments belonging to invading bacteria. The sore throat, the heavily coated tongue, the sluggish bowels and the rheumatic pains of such patients, as the case in hand, also point to the alimentary canal as the seat of the disturbance. In the chronic cases the alimentary disturbance is too slight to be clinically appreciable, but the success achieved by such antifermentative drugs as arsenic, bichlorid of mercury[13] and the salicylates, salol (phenyl salicylate[14]), salicin,[15] in both acute and chronic cases, is a further weighty argument in support of the theory that the disease is a toxemia produced by some ferment in the alimentary canal.

2419 California Street.—937 Ashbury Street.

ABSTRACT OF DISCUSSION

Dr. D. W. Montgomery, San Francisco: That lichen planus is a constitutional disease there is no doubt in my mind. This also is the conclusion reached by Engman in a paper which will shortly be published, and the proofsheets of which he showed me. The generalization of the eruption, its pruritic character and the internal distress it gives rise to, is greater than could be explained by regarding the disease as being one of the skin alone. The distress of the itching is much more acute than that of scabies or any of the parasitic diseases of the skin. And besides, the patient is "bothered" internally as well as externally.

Another point is the striking results obtained by the internal administration of drugs, such as the bichlorid of mercury, salicin, aspirin and salol and, in some cases, arsenic; and this would lead one to suppose that these drugs act as eliminants of toxins, or that they destroyed something that produced toxins. The results of such treatment are all in favor of this being a constitutional disease. The same therapeutic effects are not so frequently observed in the more chronic, slower forms of the disease, because there is not enough toxin to produce these acute symptoms. Sometimes there is extensive lichen without itching, which shows that the patient does not react pruritically to the toxin, but does react papularily.

[13] Charles J. White (Jour. Cutan. Dis., November 1908) says that to vanquish the old disease lichen planus he makes use of the old drug, mercury, with great success, and attributes the result probably to the stimulating effect of this metal on the nutrition of cells.

[14] After two weeks of ineffective treatment with arsenic. Hartzel found that salicylate of soda did well, especially allaying the severe itching. He also found that on giving salol on account of rheumatic pains in the knees, the cutaneous symptoms were relieved. Am. Med. Jour., July 20, 1907, p. 225.

[15] Radcliffe-Crocker (Brit. Jour. Dermat., February, 1908, p. 47, advises salicin in lichen planus of the acute type.

Dr. John A. Fordyce, New York City: This paper recalled a case that I reported to the American Dermatological Association ten years ago, one of universal lichen planus, with death. In that case there were profound constitutional symptoms, with fever and chills and successive outbreaks of the eruption. The autopsy showed marked changes in the heart muscles, in the blood vessels and in the adrenals. There was marked pigmentation of the skin, which was almost black at the sites of eruption, and it occurred to me that it was possibly the involvement of the adrenal bodies that led to this pronounced pigmentation. The involvement of the mouth and vagina spoke in favor of the constitutional nature of the disease. The resemblance of this affection to syphilis and the fact that it yields at times to mercurials suggest that it may be due to a spirochete or at least to some organism of that nature. Another interesting point in connection with lichen planus is the fact that the lymphatic nodes are sometimes enlarged. I have frequently noticed this involvement in cases of lichen planus of the chest and abdomen.

Dr. Louis A. Duhring, Philadelphia: A number of points occur to me in connection with this subject, and to a few of these I wish to allude. The class of cases to which this belongs is familiar to me, and I recall one case referred to me by Dr. Tyson which was almost identical with the one described by Drs. Montgomery and Alderson. Judging from my clinical experience and observation rather than from what I have read, there are two distinct clinical types of cases which occur under the head of lichen planus. From the photograph shown, as well as from the description, I think that there could be no mistake about the diagnosis in this case. In one of the types of this disease the lesions assume a sluggish, chronic character. more or less gradually attacking certain regions or localities by preference. This type of lichen planus is well known; better far than that just described by the writers. In the first, chronic type the disease continues a slow course and behaves differently, and is also amenable to a different form of local treatment from the acute type. The lesions are usually angular and flattish, instead of acuminate or rounded, as in the acute variety.

The second type, of which the case just reported is an illustration, is the acute form. The eruption appears generally suddenly or rapidly, spreads slowly or quickly, and may be almost universal, if not entirely so. The pruritus is often intense, the lesions may not be at all flattened, and are apt to be acuminate, occurring for the most part over a large area. In addition to the pruritus, there are marked general symptoms. with great nervous excitation or depression. The nervous system is always at fault in these cases of generalized or diffuse lichen planus. In the treatment of this variety arsenic has usually signally failed to benefit, and has been distinctly inappropriate in many instances. In the case I have in mind, arsenic was not at all tolerated, as the stomach and digestive tract were much involved through depressed nerve force. After the condition of the stomach was improved by rest, hygienic and other measures, the arsenic was tolerated and may have aided in the recovery. I do not think it at all likely to confound this second form with syphilis, although the eruption may look something like it. Still, I have never seen any cases of this kind that could be confounded with syphilis. I desire to direct attention to this second acute generalized form of lichen planus, because I do not think it is so well understood as it should be. In the case I referred to, the gentlemen who saw the case before me did not seem to make the diagnosis and were disposed to regard the eruption as syphilitic.

Dr. Ernest Dwight Chipman, San Francisco: It certainly seems that there is a definite resemblance in many instances between lichen planus and syphilis. I would like to record briefly a case that came under my observation several months ago; a case which was touched on by Dr. Alderson in his paper as having been pronounced lichen planus by two dermatologists, and in which the Wassermann reaction was subsequently obtained. The patient was a robust Italian, aged 35, who gave absolutely no venereal history. He had a generalized eruption, partially macular, partially papular, with intense pruritus. Here and there were seen evidences of lichenification, involving particularly the axillæ and the flexor surfaces of the elbows. The patient was seen by a confrère who made the diagnosis of lichen planus. I could not agree with him, although the eruption was suggestive of that affection. A Wassermann test was made and was strongly positive, and an examination of the contents of several of the papules showed the presence of spirochetes.

Dr. George Pernet, London, Eng.: I have had several cases of acute lichen planus, and I agree that they are among the most troublesome cases that the dermatologist can have to deal with, especially on account of the tremendous pruritus and the depression of the nervous system. With regard to the distribution of the eruption in this case, I was interested to observe that on the anterior surfaces of the forearms it terminated rather abruptly. I have seen this in several cases, not only of acute lichen planus, but also in the stage of syphilis in which the eruption is not completely developed. In acute lichen planus it corresponds with the nerve distribution. In one case at the University Hospital the palms of the hands were severely involved, with marked swelling and hyperkeratosis. In the treatment, there is no doubt that salicin has almost a specific action in these cases. In acute or subacute lichen planus I think that arsenic in any form is contraindicated; in fact, in all skin eruptions of the acute or subacute type I have found that arsenic, which is so commonly prescribed in skin affections by men not conversant with dermatology, aggravates these cases very much indeed.

The appearance of the plasma cells in this case raise the interesting point that some of these acute conditions do lead to plasma cell formation. I have noticed in acute lupus erythematosus of sudden onset the presence of plasma cells in some of the sections.

Dr. Philip Kilroy, Springfield, Mass.: Apropos of the possibility of this affection being of syphilitic origin, as suggested by its pathology, I have had two indubitable cases of syphilis in which there was intense itching. I do not think there is any dermatosis that may not itch, and itch severely.

Dr. Harry E. Alderson, San Francisco: Of course, we considered the possibility of this being a case of lichen planus engrafted on a syphilitic basis. The finding of the positive Wassermann reaction, and certain rather atypical appearances in the histologic features seemed to point that way, but clinically there was no doubt about the diagnosis of the case. Every one will acknowledge that when the clinical evidence is sufficiently strong, it will outweigh the evidence given by the microscope. Of course, a careful search was made for the spirochetes with the dark-field condenser and by smear methods, and had they been present they would doubtless have been found. In the case mentioned by Dr. Chipman I was not aware that the spirochetes had been found.

Milk and Pasteurization.—M. J. Rosenau, in *Annals of Medical Practice*, states that harm has been done by the misleading use of the term "pasteurized milk." Popularly, this has been construed to mean a superior quality of milk in the sense that antiseptic surgery is a great advance on the old-time methods. "Pasteurized milk" really means heated milk and is not necessarily synonymous with "clean milk," "good milk," or "pure milk." The particular object of the heating is to destroy the harmful bacteria. In order to correct this misconception concerning pasteurized milk, it would be better to discontinue the use of the term and substitute therefor the name, "heated milk," stating the degree of heat and time of exposure on each bottle, as well as the date on which the milk was heated.

BROWN-TAIL MOTH DERMATITIS

REPORT OF A CASE [*]

ALFRED POTTER, M.D.
Instructor in Diseases of the Skin at the Long Island College Hospital
BROOKLYN

THE BROWN-TAIL MOTH

The brown-tail moth or *Euproctis chrysorrhœa* was one of the first insects destructive to fruit-trees to be described by entomologists. The moth is a native of Europe and is common in all parts, except the extreme north. It is said that it first invaded this country in 1892, infesting a small territory in the vicinity of Somerville and Cambridge, Mass., the method of introduction being the importation of some roses from Holland by a Somerville florist.[1]

It was not until 1897, however, that any scientific investigations were made concerning the insect in this country. At this date the Massachusetts State Board of Agriculture pursued a series of investigations to discover the insect causing the destruction of vegetation in and about the suburbs of Boston and proved the brown-tail moth to be the pest responsible for the trouble. The gypsy moth commission, which was at this time actively engaged in the destruction of the gypsy moth, another pest, helped to limit the spread of the brown-tail moth also; but in 1900, when, owing to lack of appropriation, this commission was forced to discontinue its work, the moth marched rapidly onward in its destruction, traveling northward through New England into Canada.[2]

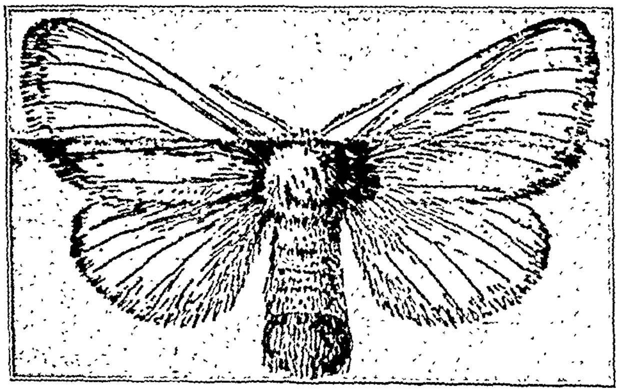

Fig. 1.—Female brown-tail moth.

The brown-tail moth is an insect which feeds principally on the foliage of fruit trees. Its average size at full growth is about one and one-half inches in length. The head is a light brown color mottled with areas of a darker brown with reddish-brown hair scattered over the surface. The body is almost black in color, with many fine lusterless, orange or silvery gray spots scattered over it. Long, finely white branching hairs arise from the upper side of the lateral tubercles. The female is almost snow-white. There is a tuft of thick brown hair on the tail of the moth, most marked on the female. The hairs are brittle and easily detached. Both male and female are free flyers and strongly attracted by light.

The moth lays three or four hundred small round eggs thickly covered with brown hairs which are dislodged from the abdomen of the moth and adhere to the eggs. The eggs are laid in July and are generally deposited on the under surface of the leaves of fruit and shade trees, forming a mass about three-quarters of an inch in length and one-quarter of an inch wide. They are hatched in about a month and the young caterpillars, forming colonies, spent the rest of the season spinning their winter webs. At the beginning of cold weather they disappear within their nests, closing the holes behind them. Here they remain only partly grown until early spring, when they come forth and grow rapidly, eating the buds and young blossoms from the trees as they appear.

The caterpillar reaches its full growth some time in June. It is about two inches in length, light brown in color with a white stripe on either side. It spins a loose cocoon and goes into the pupa stage and the moths emerge about the middle of July.[3]

BROWN-TAIL MOTH DERMATITIS

Description.—The dermatitis produced by the brown-tail moth is of two types, mild or limited and severe or extensive. In the mild form the lesions appear first as erythematous macules, few in number and situated on the face, neck and arms, sometimes spreading to the chest and back. The lesions are characterized by itching of a varying degree, depending on the extent of the eruption, which at times is almost unbearable. The macule soon becomes urticarial in character, raised above the surface, firm in consistency and disappears on pressure. The wheals are about the size of a pea, discrete as a rule and remain from a few hours to a few days. The severe type of eruption is characterized by a much more intense inflammation of the skin, a confluency of the lesions and an increase in the intensity of all the symptoms. In exceptional cases eczema is superimposed on the dermatitis and the condition becomes proportionally serious, with thickening of the skin, exfoliation and fissuring in the joints. In prolonged and severe cases the general health is sometimes seriously affected by the loss of sleep and appetite and the disturbing pruritus.[4]

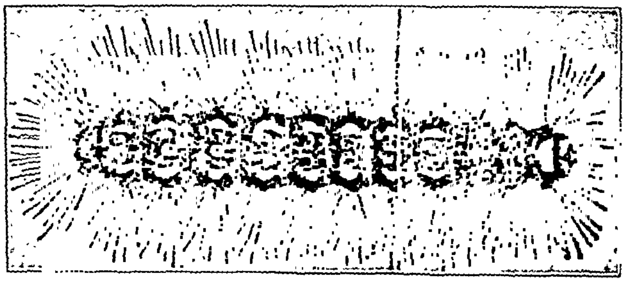

Fig. 2.—Full-grown caterpillar of brown-tail moth.

Etiology.—The lesions are produced by the tiny barbed hairs which grow on the caterpillar. The hairs are few in number during the early life of the caterpillar, but become more numerous as it reaches its full growth. These nettling hairs are straight, slender, needle-pointed rods having three rows of recurrent barbs, which average from four to five millimeters in length. The hairs are found on the moth and also in the structure of the cocoon, so that contact with the insect during any of its stages is liable to produce the disease. The hairs retain their irritating properties for a long time and the dermatitis has been caused by the handling of cocoons several years old. In the mild cases of poisoning there is generally a history of the removal of a caterpillar preceding the eruption, while the dermatitis of severe form seems to be contracted by the prolonged irritation of the skin from the hairs which become lodged in the clothing from the moths or cocoons.[5]

[4] White: Boston Med. and Surg. Jour., 1901, cxliv, 599; Towle: Boston Med. and Surg. Jour., Jan. 19, 1905.

Pathology.—It was originally supposed that the irritation was purely a mechanical one caused by the inflammation under the skin of the peculiar barbed nettling hairs, but Dr. Tyzzer of Boston has practically proved by a most interesting series of experiments that the process is a chemical one. He has demonstrated that when the nettling hairs are mixed with a drop of blood the rouleaux of red blood corpuscles break down. The corpuscles become coarsely crenated; the crenations are then changed into slender spines and finally the corpuscles become spherical. The process does not, however, go to hemolysis. Further experiments show that the irritating properties of the hairs are destroyed when subjected to a dry heat of 115 C. and that they also fail to react with the red blood corpuscles, although the structure of the hairs is not destroyed even when heated to 150 C.

Prognosis.—The attack of dermatitis produced by the moth lasts from a few days to a week in the mild cases, but the severe form often lasts for six or seven weeks. The general health is not affected except in severe cases. Attacks recur whenever exposure to the poison takes place.

Treatment.—The affection responds readily to mild soothing antipruritic lotions or salves, except in the severe cases, when more persistent treatment of stronger remedies is sometimes required.

REPORT OF CASE

During the early fall of 1908 there was brought to my notice about sixty-odd cases of this disease occurring in the Annapolis Valley, Nova Scotia. The patients all gave a similar history as to the manner of contracting the disease and the course of the trouble. Most of the cases were of a moderately severe type and were contracted from the moth or the handling of cocoons. The following is the history of a severe case:

Patient.—R. W., aged 17, was a Canadian by birth and agricultural student by occupation. The boy's older brother had recurrent attacks of eczema from infancy until 5 years old, but had had no recurrence since and was now 20 years old. The father had had a number of attacks of ivy poisoning. The family history was otherwise negative. The patient had always enjoyed good health, but had thin, tender skin with a tendency to seborrheic dermatitis. Two years before the present illness he had a severe seborrhea of the scalp, losing a considerable amount of hair. The condition improved readily under treatment and he had since been free from trouble.

Present Illness.—This began in the summer of 1908, while the patient was engaged in picking cocoons from the fruit trees. The boy was first troubled with an itching of the arms and face. Shortly afterward he noticed small red spots appear on the same locations. The spots, he said, were not elevated at first, but soon became papular. The itching increased and the lesions extended to the neck, body, thighs, nates and legs. The itching became intolerable so that he was unable to sleep at night. He would often put on his clothes and walk for miles in the middle of the night. He applied home remedies without relief and his condition became steadily worse. When he presented himself to me for treatment his whole body was involved. The dermatitis was eczematous in character; the skin was intensely inflamed, hot, dry, harsh and thickened; the flexor surfaces were fissured and painful, and on removing the clothing a shower of fine exfoliating scales would drop to the floor. The patient's nervous system was greatly impaired from loss of sleep and persistent pruritus. He had lost some weight and his mucous membranes were pale and anemic.

Treatment.—The boy immediately discontinued his work. His underclothing was boiled thoroughly to prevent any irritation from hairs lodged therein. He was put to bed and wrapped in cloths saturated in sweet oil to which had been added 2 per cent. of phenol. The itching stopped almost immediately and the patient had a good night's sleep. In one week's time the exfoliation had ceased, the skin was more soft and pliable, less red and inflamed and the tenderness and itching had disappeared. The patient was now given zinc oxid ointment containing phenol and menthol. This was continued for four weeks with an occasional bran or soda bath when the skin had regained its normal condition and the patient felt perfectly well. He returned to his employment with instructions to be careful not to come in contact with the moth in any of its stages and has since been free from any trouble.

Very little reference has been made in the medical literature regarding the brown-tail moth. Dr. J. C. White,[4] in 1901, first reported a number of cases of dermatitis produced by a caterpillar. The type of eruption and the history of the disease was similar in all cases. Dr. Meeks[1] at this time asserted that the eruption described by Dr. White was due to the hairs of the brown-tail moth. Dr. Harvey P. Towle,[4] in 1905, gave an excellent account of the history of the moth and the eruption produced by it. Most of the cases he described, however, were of the mild type. Dr. Towle was convinced from his investigations that the irritation is a mechanical one due to the barbed nettling hairs.

The article[5] read by Dr. Tyzzer of Boston before the Dermatological Congress in 1907, besides giving a valuable description of the life history of the moth, proves without doubt that the irritation is a chemical one due to some poisonous substance contained within the hair.

ABSTRACT OF DISCUSSION

Dr. Clarence M. Casselberry, Boston: Some years ago we had this plague in Boston, and most of the work that has been done on this subject has come from New England, so that we are naturally interested to hear the experience of others. I know that the devastations of these moths extended as far north as Canada and that they proved a terrible pest. Dr. Potter emphasized the fact that this dermatitis affected more particularly those who handled the cocoon. That may possibly be so, but it seemed to me that during the epidemic in Boston no one was exempt; people on the street who had never touched a cocoon became infected.

Dr. William A. Pusey, Chicago: Dr. Potter has done the section a distinct service in bringing this subject before us. It is the first paper we have ever had on this subject. Two or three years ago we did not know what this form of dermatitis was. In the West we have thus far been exempt from it, but some of our Boston friends are prophesying that this brown-tailed pest will soon cross the Alleghanies, and we are at least glad to be forewarned.

Dr. Alfred Potter, Brooklyn: I did not mean to give source of the infection. The severe cases are the result of constant irritation and the hairs from the moth and cocoon which become lodged in the clothing produce this prolonged irritation, whereas the caterpillars are brushed away as soon as they are noticed, and the infection is, therefore apt to be less severe.
the impression that it was the cocoon only that was the

IODODERMA BULLOSUM HÆMORRHAGICUM*

WILLIAM S. GOTTHEIL, M.D.
NEW YORK

Though Jarisch[1] asserts that the pemphigoid eruption occurs not infrequently from iodin and Thiberge[2] speaks of it as not very uncommon, both the recorded cases and every-day experience show it to be rare. Most instances have been seen in patients affected with renal or cardiac disease, or both; and the connection between the two conditions is apparent when we remember that iodin is chiefly and rapidly excreted by the kidneys. Most of the cases, also, have been rapidly fatal, the iodic intoxication, in combination with the visceral lesions, leading to speedy death. Thus in Wolf's case[3] a patient affected with both cardiac and renal disease took 30 grains of potassium iodid daily; for some time there was a very abundant bullous eruption, and the patient died on the eight day. Polland[4] had a patient affected with chronic nephritis, who took 1 gram of sodium iodid daily for ten days. A bullous eruption appeared on the face, neck, and hands; death occurred in a few days; and the autopsy showed the presence of bullous lesions on the gastrointestinal mucosæ. That the drug has an injurious effect on the vessel walls is shown by the rather frequent occurrence of iodic purpura.

A hemorrhagic bullous eruption necessarily betokens a systemic reaction of the intensest kind to the drug. Its rarity is evidenced by the fact that I have been able to find only three recorded cases.

CASE 1.—Reported by Morrow.[5] The patient, a man, aged 50, had taken about 200 grains of iodid of potassium in three days when a pustulo-bullous eruption developed on the face. The iodid was continued for ten days, till 900 grains had been taken. Sanguineous bullæ appeared on the face, hands and forearms. There was great prostration, stupor and involuntary evacuation of urine, this latter being acid, 1010, and containing 10 to 15 per cent. of albumin, a few pus and blood cells, but no casts. There was mitral insufficiency. Improvement of the skin eruption took place under carbolized petrolatum for twenty-six days; the general condition was unchanged; ten days later there were involuntary evacuations, and death occurred from edema of the lungs. Autopsy showed dilatation and enlargement of the left heart, mitral insufficiency, atheroma of the aorta, edema of the lungs, and chronic granular nephritis. The skin eruption reached its height five days after the iodid was discontinued.

CASE 2.—Reported by Hallopeau and Lebret.[6] This case had been presented to the *Société de dermatologie et de syphiligraphie* by Du Castel in 1896, 1899 and 1901 for hemorrhagic efflorescences on the limbs following the administration of iodid of potassium; the patient was a hereditary syphilitic. On August 7, 1903, for a recrudescence of his trouble, he was given 45 grains of iodid; the next day hemorrhagic bullæ developed on his hands. While the further history of the patient is not given, he presumably recovered from the attack. There is a cast of the eruption in the Baretta museum.

CASE 3.—Reported by Russell.[7] A man of 68, suffering from chronic rheumatism, was given iodin to the amount of 15 grains in three days. There appeared a large bullous eruption, especially on the face, the blebs containing a bloody fluid. The oral mucosa showed the same lesions, most of which ulcerated. Death occurred on the tenth day from "pneumonia and inanition." This patient had had only very small doses of iodid of potassium in syrup of the iodid of iron; yet by the third day of the medication he had coryza, conjunctivitis, hemorrhagic bullæ on the face, scalp, neck, breast, arms and legs, some as large as a quarter of a dollar, blebs and ulcerations of the lids, nares and mouth, etc.

To these I add a fourth case, seen in the service of Dr. Evans, of the City Hospital.

CASE 4.—*Patient.*—Bernard T., aged 45, admitted to Ward 2, City Hospital, New York, Aug. 18, 1898, was moderately alcoholic; had typhoid fever twenty years before admission; syphilis eight years before admission; he said he had had twelve attacks of "malaria" in the last eight years, accompanied by some jaundice; for the last ten years he had had some dyspnea and precordial pain on exertion. Three months before admission he began to feel weak, and lost his appetite; had headache, and jaundice.

Examination.—On admission the patient was found to have a pulse of 72, temperature 100, respirations 34, blood pressure 100; he was moderately jaundiced, and somewhat apathetic; no rigidity, pupils normal; lungs clear; heart showed a systolic murmur at the apex and over the aorta. The abdomen was soft, containing no masses; the liver not enlarged; the spleen not palpable; no edema: knee-jerks normal. Urine: 1022, alkaline, and contained hyaline and granular casts. Red blood cells, 5,100,000; white blood count, 11,700. The diagnosis was not certain, but inclined toward uremia.

Course of Disease.—The apathy gradually increased, and by September 8 the patient was semiconscious only. There appeared to be some left facial paralysis; and this, with the gradually increasing somnolence, the presence of suspicious scars on various parts of the skin, and the patient's history on admission, led to the suspicion of the presence of a gummatous brain affection, and on October 24 he was put on the iodid of potassium in doses of 100 grains a day. On the 25th, after he had taken his first 100 grains, a few small "blood blisters" appeared on the left hand and on the left side of the neck. There was also some conjunctivitis. By the 29th the blisters on the neck were retrogressing, and there was a marked iodin acne of the face. Small hemorrhagic vesicles appeared on the backs of both hands and forearms, and these increased in size and number rapidly. By October 20, there being no improvement in the patient's condition, the iodid was stopped; he had then taken some 600 grains altogether; and at that time photographs were taken from which the accompanying illustrations were made. The patient was quite somnolent, but could be roused; he had involuntary evacuations; and besides the lesions on the backs of the hands to be described, he had a few bloody vesicles on the neck and on the legs. On the backs of both hands were a number of variously sized and shaped tense bullæ; most of them were over the second phalangeal joints of the fingers. The smallest and most recent were pin-head to pea-sized acuminate vesicles, purplish in color, and with a distinct erythematous areola. The larger and older ones formed tense hemispherical or elongated bullæ an inch or more in size. They were of a peculiar purplish red color, especially at their bases, and with a whitish or milky aspect at their tops, evidently due to the epidermis. Puncture of the bullæ evacuated a non-coagulating blood-like fluid, which under the microscope showed the presence of red and white blood cells. There were no eosinophiles in this fluid; and the chemical test for iodin in it was negative. During the next few days these bullæ increased very much in size and became confluent; new ones appeared, and finally the entire backs of the hands were covered with immense confluent sanguineous blebs. Some of these ruptured, leaving extensive excoriated and readily bleeding surfaces behind; and others became infected and purulent. Toward the end the entire backs of the hands and forearms were one large raw surface. A few fairly large bullæ of precisely similar nature appeared on the face and legs. By November 7 the stupor deepened, and on November 10 the patient died comatose. It is worthy of note that there was not a single bulla or vesicle on the palms, and that, while there were a very few hemorrhagic bullæ on other parts of the skin, as noted above, the entire brunt of the dermal explosion was on the backs of the hands and the forearms.

Autopsy.—This showed many lesions of the internal organs: in fact, the patient was in the condition of many of those who come to spend their last hours in the great charity hospital. The immediate cause of death, as reported by the pathologist, was edema of the lungs, though the house record says nothing of this. The essential disease of which the patient died was syphilitic cirrhosis of the liver; but besides this he had hypertrophy of the left ventricle; dilated mitral ring with regurgitation; fatty degeneration of the heart muscle; emphysema and terminal edema of the lungs; chronic interstitial splenitis; atrophy of the suprarenals; chronic degenerative nephritis; chronic interstitial pancreatitis; enlarged abdominal lymphatic glands; chronic peritoneal and pericardial adhesions, and smooth atrophy of the larynx; not to mention a number of less important changes and degenerations. In spite of the official postmortem designation of the liver disease as the cause of death, the medical men who observed the patient during his last illness were of the opinion that the patient died of uremia.

Iodin, as is well known, is one of the most rapidly absorbed and excreted of medicaments. All the mucosæ take it up very quickly; and so does the skin under proper conditions, as Welander[8] and Hirschfeld and Pollio[9] have shown. Lang[10] has demonstrated iodin in the blood from one to ten minutes after its ingestion, and a little later in the saliva, and still later in urine, gall and milk. In one hour it has disappeared from the blood; in twenty-four hours it has almost gone from the secretions, though a little of it may remain for weeks, to be slowly excreted by the kidneys. Any serious obstacle, therefore, to the rapid passage of the drug through the organism must lead to its accumulation in the tissue fluids.

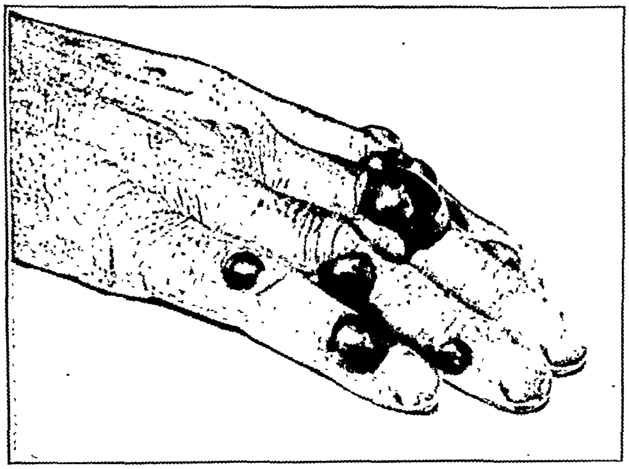

Fig. 1.—Author's case of iododerma bullosum hæmorrhagicum. Photographed three weeks before death.

It is generally held that the effects of the iodid medication, therapeutic and toxic, are due to the free iodin that is liberated in the blood from the various compounds employed. The exact manner in which the change occurs is still unsettled; but it seems probable that the theory of Binz[11] is the correct one; that in the presence of oxygen in the blood and carbonic acid in the tissues a salt such as potassium iodid is transformed into potassium carbonate and iodin is set free. At all events, free iodin is demonstrably present in the blood and acts as an irritant to the cells with which it comes in contact, exactly as it does to the dermal and mucosal cells when applied externally. Sajous[12] holds that the *iodin is taken up by the leucocytes and irritates the intima of the vessels*, causing their contraction and thus increasing blood pressure. This does not, however, to my mind, satisfactorily explain the marked vascular symptoms of acute iodism; and I am more inclined to agree with Thin,[13] who recognizes a distinctly disorganizing *effect of the iodin on the epithelia of the blood vessels*. The various dermic iodic reactions, the acne with its limited edema and congestion, the pemphigus with its effusion of serum and formed blood elements, the purpura with its extravasation of blood, the congestion and hypersecretion of the various mucosæ, the hemorrhages from the internal organs, etc., are all explainable in the same way.

The main avenue of iodin excretion being the kidneys, organs with a capillary circulation perhaps the most extensive and complicated in the body, and the free iodin itself having a directly deleterious influence on the small vessels themselves, it is not strange that the renal system should be an early sufferer from the iodin poisoning. I have made it a practice for a long time past to have regular urinalyses made in patients undergoing the iodid treatment, and I have noted the fact that in most cases, even in young and otherwise healthy individuals, there were signs of renal irritation at times. Patients without a trace of nephritis previously showed albumin in varying amount and hyaline casts at times. In fact, I think it desirable to keep track of the urine when administering an intensive iodin course, and to decrease or stop the exhibition of the drug when the excretion shows that the renal functions are being seriously interfered with. I am afraid also that I have seen a number of cases of permanent damage to the kidneys that I have been unable to ascribe to anything but the iodin medication.

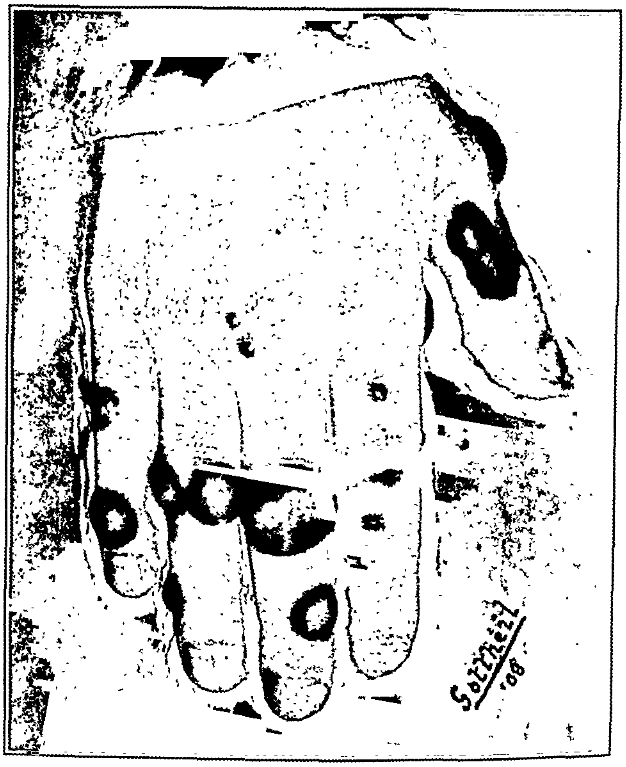

Fig. 2.—Cast, taken three weeks before death.

If the healthy kidney is liable to be injured by iodin the drug has naturally a still more deleterious effect when that organ is already damaged. Here there is a true vicious circle; the damaged emunctory prevents the normally rapid excretion of the drug, so that it is kept in prolonged contact with the tissues; and the irritant drug still further injures the excretory organ. The intimate relationship of iodism and chronic nephritis has long been recognized, and has been insisted on by many writers, among whom Duckworth asserts that iodin is dangerous in these cases, George Johnson notes the frequency of severe iodism in Bright's cases, and Stewart says that there is abundant proof that the more kidney elimination is hampered the greater the danger of iodism. Ehlers, as the result of his experimental work, comes to similar conclusions. The great majority of cases of severe iodism, the cases with bullous and hemorrhagic eruptions, have occurred in patients suffering from renal insufficiency.

ABSTRACT OF DISCUSSION

DR. F. C. KNOWLES, Philadelphia: During the past two years I have had the opportunity of seeing at the Pennsylvania Hospital two cases of simple purpura caused by the internal use of the iodids. The cause of the eruption was proved by the fact that, after the drug was discontinued and the eruption had disappeared, it reappeared after the use of small doses.

DR. GEORGE PERNET, London, Eng.: I agree with Dr. Gottheil that bullous eruptions after the administration of the iodids are rare. I cannot recall any case of the hemorrhagic type like the one he described. Potassium iodid is frequently given in much too large doses, and without any reference to the state of the kidneys. Of course, potassium iodid is of itself a diuretic, and even small doses may at times do harm. Certainly some of the heroic doses are really not indicated.

DR. WILLIAM A. PUSEY, Chicago: During the past year I have had a fatal case of the same sort, and a more desperate picture of disease I have never seen. The patient was admitted to my service at the Cook County Hospital without diagnosis, but my interne, who had seen one or two similar cases during the previous month, made the diagnosis. The patient was a woman who had taken moderate doses of potassium iodid—so far as we could determine, from 7½ to 10 grains three times a day. When admitted, she presented hemorrhagic bullæ which would become blackish in color and flaccid. Then the base of the ulcer would become gangrenous, and from the sides of the ulcer a small bullous collar three or four inches in diameter would develop. Iodin was recovered from the patient's urine. She lived six or seven days after I saw her, and about ten days after the first history of the eruption. Dr. Charles J. White of Boston has reported an almost identical case.

Recently I was asked to make a diagnosis in a case in which the diagnosis of congenital syphilis had been made. This patient, a child, had hypertrophic lesions, and syphilis could be readily eliminated because of the distribution of the lesions. There were no lesions about the mouth nor buttocks. The eruption was distinctly different from that of syphilis, and there had been large ulcerative lesions, as shown by the scars. In that case the child, a nursing baby, had received the iodin through the mother's milk. In this case also, iodin was recovered from the urine. The child died in a few days with bronchopneumonia but really from the iodism.

DR. W. S. GOTTHEIL, New York City: In the City Hospital in New York, which is the great venereal center for this part of the country, the tradition still holds that it is necessary to give enormous doses of iodin, in some instances from 750 to 800 grains daily, and we think we get good results from this. In one case I gave 1,000 grains daily, and when I was interne I can recall a case of gumma of the brain in which as high as 1,200 grains daily were given. I would simply emphasize the advisability of keeping close watch on the urine while giving potassium iodid, especially if the dosage is large.

THE WET DRESSING IN SURGERY [*]

CHARLES A. PARKER, M.D.
CHICAGO

In our eagerness to avail ourselves of the many new and sometimes very promising announcements in surgical progress it is well not to discard too lightly older methods and principles founded on long-established and successful usage. Into the field of treatment in recent years the hyperemia of Bier and the vaccine therapy of Wright have entered as active participants for our favor in the care of infectious processes. So prominent a position have they occupied that frequently other methods have been completely overshadowed, to the serious neglect and injury of the patient. With no desire to detract from all the demonstrated and promised virtues of these newer methods of treatment, I do wish to preserve the wet dressing from even the momentary neglect that threatens it and to place it in the proper rank to which its broad range of usefulness and long record of success entitle it.[1]

Of course, any method of treatment will suffer undeserved censure when ignorantly or improperly used. Surgical measures are most efficient in the hands of a surgeon, a knowledge of surgical conditions and processes necessarily forming the basis of treatment. The automatic dressing has not yet appeared.

Little that is new can be said in support of so well known a measure; but, in view of its importance and the absence of any recent comprehensive review of the subject, it appears particularly apropos to present it now on its own merits and in relation to other measures that its present adherents may be even more firm in their faith and its future usefulness greatly extended. Continued experience with surgical material convinces me that it is not so generally employed as it should be.

DEFINITION

By the wet dressing is meant the simple form of surgical dressing consisting of plain sterile absorbent gauze, wrung out of sterile water or physiologic salt solution, covered with an impervious tissue, as paraffin paper, oil silk or gutta percha tissue, and held in place by a bandage. The gauze is usually wrung out of warm water and applied in several layers over the affected part, and is then covered with the impervious tissue, which extends beyond the margins of the gauze, so that when the bandage is applied the moisture in the gauze can not evaporate and the dressing will be as wet the day after as the day it was applied. The gauze is usually wrung as dry as possible by the ordinary means in the dressing room. When thus applied to a secreting wound it very readily absorbs the secretion, a property wholly lacking in a saturated dressing. Powders are unnecessary, nor need various aromatic and odious preparations be applied. Plain sterile water or physiologic salt solution is preferable to antiseptic solutions for moistening the gauze.

ILLUSTRATION OF USES

In Lacerated and Contused Wounds.—These wounds are of various degrees, from the crush of the boy's finger in the cogs of his "Irish Mail" to the loss of a limb in a railway accident. Taking the finger for an example, the tip is lacerated, the nail may be lost and the bone broken. With surgical cleanliness the hopeful parts are laid together, possibly stitches placed for better control of the fragments, and the whole put up in a wet dressing. Within the next twenty-four hours, when the dressings are removed, the parts not too severely crushed have regained much of their color, while the necrotic portions soon become manifest. Every living bit of tissue has a chance to live and grow, and the facility with which the dressing is removed is a revelation.

---

[1] Since preparing this paper two interesting complementary articles on allied subjects have appeared in recent journals. One is by H. G. Wells on "The Resistance of the Human Body to Cancer," in THE JOURNAL A. M. A., May 29, 1909; the other is by Simon Flexner entitled "Natural Resistance to Infectious Diseases and its Reinforcement," Popular Sci. Monthly, July, 1909.

The finger is again similarly dressed and redressed till the last slough has separated and the epithelial covering is complete. The same dressing is equally applicable to and indicated in the crushed limb or similar wounds occurring elsewhere in the body. In wounds of deep tissues and organs, where dressings in general are either not directly applicable or are not desirable, the use of the wet dressing is also equally limited by the same restrictions. As a matter of fact, these deep wounds are under the influence of the natural heat and moisture of the tissues, though frequently lacking in facilities for relief of irritants and tension.

In Local Infections.—The common infections of the hand serve as useful illustrations of its application in pyogenic infections. These include the various classes of panaritia, or felons, palmar infections—intra- and extra-thecal—and the lesions of bones and joints. Suitable operative or mechanical measures having been instituted, the best local application is the wet dressing. Take, for instance, the simple painful paronychia, or ungual panaritium—the so-called "run-around" of the nail—frequently resulting from an infected hangnail. Pus is commonly in evidence, but the hard and dry skin clinging firmly to the nail keeps up the pressure and the symptoms; or, the pus may be discharging somewhat around the nail, but periodically drying up and clogging its own exit, causing the exacerbation of symptoms. The wet dressing applied to this finger in the one instance softens the tissues around the nail so that the pus escapes, while in the other it keeps the parts moist so that occlusion does not occur—in either case favoring the healing and relieving the symptoms. Necessary operative measures should be employed when indicated. What has been said of the hand applies with equal force and pertinency to the foot and to infections in all other equally accessible parts of the body, varying the technic according to local conditions.

Wounds in General.—In general, the wet dressing is indicated in the treatment of all open wounds or tissues deprived of their normal epithelial covering. Infected wounds of the subcutaneous or deeper tissues when incised become open wounds and are treated as such with the necessary modifications for drainage. It exerts a distinct and favorable influence on the processes of inflammation, frequently limiting and occasionally completely controlling local pyogenic processes without drainage. Here, however, is the greatest danger in this, as in other measures, that it will be used exclusively, instead of an adjunct, as it is designed to be. Aseptic areas deprived of their proper skin covering, as in incomplete plastic operations or similar surgical procedures, are best protected by this dressing. It is equally well adapted to the treatment of infected areas with suppurating or discharging wounds, as in many forms of ulcer regardless of type or origin, though not unmindful of collateral surgical and specific measures variously indicated. It is not indicated in aseptic surgical wounds where the tissues are completely covered with skin, the proper protection of the soft tissues.

MODE OF ACTION AND SPECIAL FEATURES

Its therapeutic efficiency depends on its physical features, which will be considered in detail in connection with its method of producing results in the various surgical conditions to the treatment of which it is best adapted.

Its Absorbing Capacity.—The removal of excessive or irritating secretions from a wound must be an attribute of a good dressing. Naturally, dry gauze will absorb more fluid than already partially saturated material. The practical difference, however, is not so great, as experiment shows that the wet gauze well wrung out absorbs at least three-fourths as much fluid as the dry. One ounce of dry gauze will absorb four ounces of water. When this is wrung tightly in the hands it will weigh two ounces and will absorb three ounces more of water, showing just three-fourths the absorbing capacity of the dry gauze. Under compression in an ordinary dressing the limit of absorption is somewhat reduced in both.

The important fact is that the wet dressing continues gradually to absorb to saturation, while in the dry one the secretion, unless excessive, commonly becomes inspissated and impervious a short distance from the wound, thus effectually preventing further absorption by the gauze outside the area of dried pus and blood. On the removal of a properly adapted wet dressing all the secretion comes away with the dressing, and the wound is left clear of fluid débris. Maltreated wounds and ulcers covered with various medicaments and secretions become clean with a few dressings, when the actual condition of affairs first becomes apparent. A scab never forms under a wet dressing, and one already present is soon loosened and the fluid allowed to escape. It is a prompt and ideal method of cleaning a large ulcer preparatory to skin grafting.

Heat and Moisture.—These are the most important physical factors in biology. Without moisture cell growth is impossible, while a temperature near that of the body is necessary for best development. Next to the skin itself, the wet dressing furnishes the ideal condition for cell growth. The temperature of the wet dressing, whether put on warm or cold, soon remains near that of the tissues with which it is in contact, the impervious covering preventing evaporation and dissipation of the heat acquired. A scab is not formed and the tissues are always moist with serum or the isotonic salt solution, further conditions favoring maximum growth of granulations and epithelium. Owing to this condition, mechanical drainage can be reduced to a minimum or dispensed with entirely, as the edges of the wound do not readily adhere after incision and the slight pressure of retained secretions easily opens it. The ease and comfort with which this dressing can be removed from a raw surface or inflamed region are in themselves no small blessings. It requires no tedious and anxious soaking to remove, nor does it bring away such large portions of new and precious epithelium and granulations as are lost in the removal of the dry dressing.

A refinement in its application may be introduced here that seems to be the limit of conservation of these tissues. Narrow strips of gutta percha tissue are laid directly on the granulations and new epidermis in gridiron fashion, or at right angles to each other, till the parts are just sufficiently covered to prevent the wet gauze as it is usually applied from actually touching them. The strips of rubber tissue are commonly one-fourth of an inch wide and long enough to cross the area, the object being to prevent the tissues entering the meshes of the gauze and being torn with every removal. The narrow strips are to be used instead of one large piece covering the whole area, as in the former good drainage of all secretions is maintained from the margins of the many strips, while retention is the rule with the single piece. With this refinement all the other elements of the wet dressing, the wet gauze and the external impervious covering, remain the same. In routine work this special feature is often neglected with little difference in results, as it is but a minor factor in the process, though in some chronic and obstinate cases it decisively turns the tide toward success.

To heat and moisture are the special virtues of the wet dressing chiefly due. Their mode of action deserves further consideration. The growth and repair of tissues are fundamental functions; they are part of the phenomenon of life, and to their maintenance proper nourishment and environment are the most essential factors. The dressing most nearly furnishing these essentials is the one of choice. Nourishment for the tissues comes from the blood and is principally in the form of nutritive lymph or serum. No artificial or other fluids can equal these for the purpose, and the best that can be said of any such fluids in or on the surface of the tissues is that they are bland or they do no harm. Thus, from the standpoint of nourishment, local applications have no practical value in surgery, their proper sphere being the improvement of environment.

The local lesion may result from various forms of tissue insults, mechanical, chemical, bacterial, and others. The local treatment consists in removing the aggressive factors and providing the best possible environment for the living tissues in their efforts at repair and resistance against further injury. The lesions from which the aggressive factors can be completely and directly removed are the simplest to care for, prompt growth and repair of the remaining living tissue being the rule. If the wound be closed the skin conserves the best physical condition for growth in the nutritive lymph. In the open wound this protection is lacking. The lymph is present, but desiccation soon renders it inert and destroys many cells in the exposed area. These elements eventually form a scab and prevent further destruction, cicatrization progressing successfully beneath. From various causes the scab is frequently incomplete or broken and some of the tissue continuously exposed to desiccation and destruction. Here dressings must be applied to prevent desiccation and maintain proper temperature while inhibiting trauma and infection. A well-adapted, non-irritating, impervious covering fulfills most of these requirements.

Excepting the intentional wounds of aseptic surgery, the vast majority of lesions requiring local dressings are of an infectious nature and often difficult to handle. These are the ones that demand the most of our attention, and measures that are practical and effective in their treatment deserve our confidence and support in direct proportion to their curative properties. Bacteria and their products are the aggressive factors here, and their treatment by other means than complete and direct removal or disinfection—in which case they become aseptic lesions—is the treatment under consideration.

Action of Antiseptics.—In some specific infectious lesions, medicinal substances entering the general circulation exert distinct local curative influences. A study of the best known and most efficient antiseptics will throw much light on the specific action of the group in general in local applications. Foremost among them are the salts of mercury, of which the bichlorid is the one most used. Its direct efficiency under favorable conditions and its limitations in the presence of serum and pus are generally well known. In a 1 to 1,000 aqueous solution it prevents the growth of anthrax spores in from 3 to 7 minutes, while a 1 to 10,000 aqueous solution kills the bacilli in 6 seconds. A 1 to 1,000 aqueous solution kills the *Staphylococcus pyogenes aureus* in from 1 to 5 minutes, though in the presence of serum, pus or fat it is rendered ineffective in much stronger solutions. A 1 to 2,000 solution in dressings frequently excites a pustular dermatitis in previously healthy skin, and a 1 to 10,000 solution in irrigation causes local cellular necrosis on exposed tissues.[2] Thus it does not meet the conditions prescribed, that it shall destroy or inactivate the bacteria without injuring the tissues containing them. Other salts of mercury are equally wanting in this particular attribute.

Phenol (carbolic acid), its related products and derivatives, iodin and its preparations, and the various formaldehyd combinations used as antiseptics, are all more or less bactericidal, but none of them limit their injurious action to the bacteria alone; to effect their purpose they destroy the tissue and thus also fail to reach the prescribed standard. The eligible substances must pass through the vital juices between or within the cells to the sheltered bacteria and produce their specific effects without disturbing the function of the lymph or the integrity of the cells.

The physical and vital relations of the bacteria and tissues being so intimate, the one being hidden in the interstices of the other and both depending on the same pabulum for their nourishment, the achievement of such a desired result could ensue under but two possible conditions: either that the agent exert a selective action on the bacteria, or that their resistance be so much below that of the tissues that they succumb to a weak solution that is harmless to the latter. Many experiments by competent observers now render it extremely doubtful if we have a single chemical antiseptic possessing these attributes.[3] Such selective substances may eventually be evolved for local use as are now used through the circulation, as vaccines, antitoxins, etc. As the effects obtained by applied irritants increasing the local reaction, phagocytosis, etc., are not specific in their nature, though often desirable in practice, the bacteria being only secondarily or indirectly affected, this process is not to be considered in the present relation. The intelligent use of antiseptics in preparation for operative work, or with the knife and cautery where the sacrifice of some living tissue occurs in the effort at stimulation or direct disinfection to save the rest, is, of course, not interdicted. The ultimate defense of the tissues through local measures designed to directly affect the contained bacteria being at present impracticable, if not impossible, means favoring the protective power of the tissues themselves, on which reliance must eventually be placed, thus become of first importance.

---

[2] Halsted: Kelly's Operative Gynecology, first edition.

[3] Verhoeff and Ellis, of Boston, in summing up an article in THE JOURNAL A. M. A., June 29, 1907, say: "Our results seem to justify the belief that no non-irritating antiseptic can be effective in the presence of serum. . . . No chemical antiseptic can destroy micro-organisms within the tissues without injury to the latter." Sir Almroth E. Wright, London, in THE JOURNAL A. M. A., August 10, 1907, in an article on the opsonic theory, says of local antiseptics: "The antiseptic will directly antagonize the protective forces which the living organism has at command, it will paralyze the phagocytes and will abolish the anti-bacterial power of the blood fluids. This is not all; it injures the histologic elements and in particular the capillaries, leading to an outpouring of lymph, which not only washes away the antiseptic, but when the skin is in question converts it into a lymph-sodden envelope easily penetrated by bacteria."

EFFECT OF HEAT AND MOISTURE ON BACTERIA

The query naturally arises as to the effect of heat and moisture on the growth of the wound bacteria, as these physical conditions are quite as essential and favorable to the growth of micro-organisms as to that of the tissue elements. The immediate effect is a mechanical one, like irrigation, the bacteria free on the surface of the wound or floating in the serum being disseminated by the fluid throughout the capillary gauze. The diffusion is rapid and continuous until the gauze is saturated, the result being a great reduction in the number of free bacteria in direct relation with the wound and a corresponding diminution in the contained toxins. Growth may occur in the dressings on the nourishing wound secretions, but with their frequent renewal this growth is quite a negligible factor, as it is no longer associated with the wound itself. There are yet to be considered the bacteria remaining in contact with the wound and those within the tissues.

Intramural Bacteria.—These bacteria are beyond the direct mechanical as well as the direct bactericidal action of any safe application, and are affected solely by the tissue reaction, either normal or artificially stimulated.

Intermediate Bacteria.—There is a sort of middle or intermediate region between the free surface bacteria which are readily removed by fluid diffusion in the dressings and the intramural bacteria just mentioned, where bacteria are present in the most superficial layers of the exposed tissues, in the cells and their interstices, enjoying all the beneficence of applied heat and moisture while at the same time exposed to a diminishing degree of tissue aggression among the advanced guard of superficial cells and altered serum. The dead and dying cells and defective serum furnish a rich pabulum in which the bacteria may develop rapidly with the least antagonism on the part of the tissues. This is the region of advancing granulations and will remain the one of greatest bacterial accumulation and growth. When the accumulation exceeds certain local limitations the excess becomes superficial and is removed, or intramural and is antagonized, an automatic arrangement that confines this accumulation to rather narrow and definite limits. The bacteria that become intramural are subject to the same influence as others of their class, the much larger number that become superficial from the absence in this direction of tissue resistance are removed and cause no further trouble, the constantly changing original zone still remaining the center of active growth and distribution.

In closed infections greater extension of the bacteria into the tissues is favored by the absence of a free surface and diminished tension toward which growth preferably occurs. In some virulent types of infection, as hydrophobia, malignant edema, etc., and other infections in profoundly altered states of tissue resistance, the dissemination of the bacteria and their products is so irresistible that a differentiation into these several zones from the standpoint of local applications becomes practically useless.

Fortunately, however, these are not the ones with which we most frequently have to deal. These three zones are influenced by the local dressing, and their control is commonly the control of the infection. The superficial, we have seen, is controlled by the mechanical action of the wet dressing; the intramural depends on the resistance of the tissues; while the intermediate is subject to both influences, their combined action eventually eliminating all bacteria during the healing.

EFFECTS OF COLD

Although practically all pathogenic bacteria grow best at or near the body temperature, most of them continue to grow at temperatures both above and below this point, and the more common ones, particularly the pyogenic, have a range of many degrees compatible with existence and development. The tissues, however, are very susceptible to changes of temperature beyond comparatively narrow limits. A reduction of a few degrees in the local temperature will seriously reduce the resistance of the affected tissues, while the bacteria will continue to develop with only a slightly diminished virulence in a practically non-resisting field with a result easily foretold.

Thus it is with cold as with the bactericides, the inhibiting influence on the bacteria is more than offset by the injurious effect on the resisting tissues. Whatever salutary influence cold may be considered to exert on the inflammatory process, it certainly should not be ascribed to any direct action of the cold on the bacteria. Excessive heat is equally prejudicial to tissue resistance. Doubly disastrous is the effect of cold when it also produces characteristic circulatory changes, further reducing the vitality of the tissues by diminishing the quantity of blood.

While heat and moisture do most favorably influence bacterial development, at the same time they secure for the tissues the highest degree of efficiency in executing their aggressive or conservative action in the ultimate struggle with invasion. It is not to be presumed that any dressing will increase the resistance above nature's normal, or the greatest degree of resistance the tissues can offer to invasion without themselves suffering injury or loss of integrity. If that can be reached, or as near as may be approached, the best possible local aid has been given. Were the virulence of the bacteria under the stimulus of heat and moisture to increase *pari passu* with the resistance of the tissues, apparently nothing would be gained by the process. While ordinarily such an increase is quite improbable, it is true that the tissue cells start with the decided natural advantage of self-protection, so that the dressing that best conserves this advantage is the most meritorious.

This is the gist of the whole matter: that which interferes with bacterial development depresses the tissues; that which favors the tissues favors the bacteria; but, as every victory that has ever been won over invasion has ultimately been won by the tissues, reason suggests and experience proves that the dressing that keeps the inherent advantage of the tissues in the highest possible physiologic condition is the one most favorable to healing. From the foregoing considerations it is my belief that the wet dressing most nearly fulfils these requirements and furnishes the nearest approach to the ideal condition for the healing of the extensive class of surgical conditions for which it has been suggested.

LIMITATIONS AND MODIFICATIONS

The wet dressing is not a panacea nor is it without faults. Aside from the evils arising from its use to the exclusion of other indicated surgical measures, it may have unpleasant effects in its usual employment. These are more particularly its macerating effect on the skin and occasionally resulting dermatitis. When it is desired to employ a wet dressing over a long period of time, or under unfavorable local conditions, the previous application of a protective salve to the surrounding region usually overcomes all difficulties, the condition resembling that of the protective vernix caseosa in the liquor amnii. Occasionally alternating the wet and the dry dressing, part of the time one and part of the time the other, is a satisfactory solution of the problem; and when the irritating effect becomes more serious than the condition it was intended to allay it is naturally interdicted entirely. In practice these objections and contraindications seldom occur, and the occasion is exceedingly rare when it can not be used advantageously during the period when its influence is most desired.

THE EXPERIMENTAL PRODUCTION OF THE MATERNAL PLACENTA

AND THE FUNCTION OF THE CORPUS LUTEUM *

LEO LOEB, M.D.*
PHILADELPHIA

In former work I have shown that it is possible to produce at will any desired number of maternal placentas or deciduomata in the guinea-pig, if we make incisions into the uterus at a certain period after ovulation. Here I shall report on the continuation of my work[1] without, however, attempting to go into any details or to give definite figures.

1. In the beginning I may state that the experimental production of the maternal placenta depends primarily on three factors: first, on a chemical sensitizing of the uterine mucosa; second, on an additional mechanical stimulus applied to the uterus, and, third, on a certain condition of the body fluids of the animal.

2. In my former publication I described only the changes produced in the guinea-pig after incisions made into the sensitized mucosa. Since then I have carried out similar experiments in rabbits and I find that in the rabbit it is also possible to produce the maternal placenta experimentally. But while in the guinea-pig the newly formed structures somewhat resemble the adrenals, in the rabbit the experimental maternal placenta is differently built. Here usually no distinct tumors are obtained, such as we find in the guinea-pig, but the histologic changes are very marked; they consist in proliferation of the surface epithelium leading often to giant-cell formation, in the production of nests of glycogen cells in the uterine papillæ and in a plasmodial transformation of many uterine blood vessels, changes also noted in the normal placenta of the rabbit. These results enable us to analyze the factors leading to the building up of the maternal placenta and to state that these structures are produced independently of any specific action of the ovum, because experimentally they can be produced, without any previous contact with the ovum having taken place. I have not yet succeeded in reproducing Minot's monster cells or the multinucleated glycogen cells. At present, therefore, we can not exclude the possibility that these latter structures may owe their origin to a specific action of the ovum.

It will be of great interest to use these methods for the analysis of the formation of the placenta in other mammalians.

3. In my former publication I stated that after extirpation of the ovaries the formation of the maternal placenta takes places only in a small minority of all cases and that in the few positive cases the resulting deciduomata are very small. Since then I have continued these experiments and in a large series I have noted that the only tissue in the ovaries which is concerned in the production of the sensitizing substance is the corpus luteum. Even after extirpation of the corpora lutea small deciduomata may be produced in a small minority of cases; and in one experiment, indeed, I found a pregnancy to be established notwithstanding the absence of the corpora lutea (which was in every case proved by examining the ovaries in serial sections). The few positive results obtained after the removal of the corpora lutea are in all probability to be ascribed to the fact that in my experiments the lutein tissue was removed several days after ovulation and at that period a partial sensitization of the uterine mucosa may very well have taken place already. In future experiments it will be necessary to remove the corpora lutea or the ovaries very soon after ovulation before the specific substance has been formed, and in such cases no maternal placentas ought to develop after subsequent incision into the uterus.

4. I have, therefore, been able to ascribe a definite function to the corpus luteum, namely, that of supplying a sensitizing substance to the uterus which prepares the latter to respond with the production of the maternal placenta, if an external stimulus of a mechanical nature is added. A number of investigators, especially Born and Fraenkel, believed the corpus luteum to be indispensable for the attachment of the ovum at the surface of or inside the uterine mucosa and consequently also for the initial stages of pregnancy. Furthermore, the periodic function of the corpus luteum was believed to be responsible for menstruation and other sexual processes. No definite proof for these hypotheses, however, has been given so far; and the experimental evidence was, on the whole, unsatisfactory. My investigations led to an exact method of experimentation which permitted us to determine definitely the function of the corpus luteum, namely, that of supplying a substance which sensitizes the uterus and thus enables it to produce the maternal placenta.

5. In order to correlate the functions of the corpus luteum and the formation of the maternal placenta it was necessary to study the growth and the retrogression of the corpus luteum in the guinea-pig. Only a few data of interest may be mentioned here. The corpus luteum in the guinea-pig is formed principally through a transformation of the granulosa cells of the follicle.

6. The formation of the corpus luteum follows the spontaneous rupture of the follicle (ovulation) which usually takes place approximately six to ten hours after copulation. But ovulation with the subsequent formation of corpora lutea may take place independently of a preceding copulation. Such a spontaneous ovulation usually occurs in the mother inside the next ten hours after the young have been born; it also occurs in many cases spontaneously—approximately nineteen to twenty-four days after a preceding ovulation without the pres-

ence of a male. But such a spontaneous ovulation without a preceding labor and without a previous copulation does not take place in every case. Under ordinary conditions the corpus luteum grows actively for approximately eighteen days; then a spontaneous degeneration and retrogression sets in. In the case of a concomitant pregnancy, however, the period of retrogression is deferred considerably and only begins sixty days after copulation or later.

7. Although the life and growth of the corpus luteum lasts, therefore, usually eighteen days, and much longer in the case of pregnancy, the uterus is not sensitized during the whole of this period, but only approximately from the second to the ninth days after copulation. If the mechanical stimulus of the uterus is applied after the ninth day, the uterus does not usually respond with the formation of a maternal placenta. This may perhaps be due to the fact that within nine days after copulation the uterus becomes saturated with the sensitizing substance and that, after such a state of saturation has been reached, fatigue sets in and the uterine mucosa becomes unresponsive. It may be that only a dynamic process, namely, the constant addition of the corpus luteum substance, has a sensitizing effect. However that may be, this curious relation between corpus luteum and uterine mucosa exists and is easily interpreted in a teleologic sense in the following manner:

8. We see that the uterus is sensitized approximately three to nine days after copulation. If we wished, therefore, to select the safest period for the egg to attach itself to a sensitized uterine mucosa and to be sure to be welcomed at its new habitat, and to find a responsive environment, we would choose the middle of this period, namely, approximately the sixth day after copulation, and this is precisely the term at which under normal conditions the ovum does begin to enter the uterine mucosa in the guinea-pig.

We have here an example of a highly useful adaptation, most important for the propagation of mammalians, and we, furthermore, recognize the fact that this adaptation is based on a biochemical correlation between different organs.

9. In this connection I may briefly mention a few other facts concerning the life-history and the possible function of the corpus luteum. The retrogression of the corpus luteum sets in apparently spontaneously at the period mentioned above; it is not dependent on nor is it caused by a preceding new ovulation and the formation of a new corpus luteum. The retrogressive changes in the corpus luteum set in even without the previous rupture of a follicle.

On the other hand, in a number of cases I found that an early extirpation of the corpora lutea led to an acceleration of the following ovulation and consequently to an earlier formation of new corpora lutea. This observation suggests that the existence of growing corpora lutea has an inhibiting effect on the growth and rupture of ovarian follicles. Such an inhibiting action does not, however, consist in a mechanical influence exerted by the corpus luteum, inasmuch as the follicles rupture as soon as the retrogressive changes set in in the corpora lutea, although the site of the corpus luteum and, therefore, its mechanical significance has not yet changed at that time. It is, therefore, a justifiable hypothesis, if we assume that the functional, probably chemical activity of the corpus luteum is one of the factors determining the time of the rupture of the follicle and the subsequent formation of the new corpora lutea. Such an influence of the corpus luteum is, however, not the sole determining, but only a concomitant factor in ovulation; it would explain why during pregnancy a further rupture of follicles usually does not take place.

10. At present we do not know why the spontaneous rupture of follicles is followed by the formation of a corpus luteum. Two years ago I carried out a number of experiments, in which at various times, preferably near the period of ovulation, I made incisions into the ovaries, in order to open follicles and thus, if possible, produce corpora lutea experimentally, but in no case did I succeed. The cuts in follicles were not followed by the formation of corpora lutea. These experiments I intend to take up again. Perhaps some variations in the technic may give positive results, but at present it appears as if only at certain periods and under certain conditions the opening of a follicle would lead to the formation of a corpus luteum.

11. Three factors are, as stated, primarily concerned in the experimental production of the maternal placenta: (1) the sensitizing substance of the corpus luteum; (2) the mechanical stimulus exerted directly on the uterine mucosa; (3) the character of the body fluids, which is more or less specific for each individual of a certain species.

It is, however, possible to make a more far-reaching analysis of these phenomena and to reveal quantitative relations between the causative factors and the size of the deciduomata.

I mentioned above that sometimes after extirpation of the corpora lutea, deciduomata develop, which, however, under those conditions were usually very small. This can best be explained if it be assumed that a relatively small quantity of this corpus luteum substance enables the mucosa merely to form small deciduomata.

In a similar manner incisions made into the uterus inside of the first forty-eight hours lead usually only to the development of small nodules, and probably for the same reason; at that period after application of the mechanical stimulus, when the uterus begins to react, only a relatively small quantity of the sensitizing substance had been secreted and had had time to unite with the uterine mucosa.

12. Definite quantitative relations exist also between the mechanical stimulus and the size of the maternal placenta.

The volume of the deciduomata grows in direct ratio to the area of the uterine mucosa exposed by the incision. The direction of the incision is, therefore, of importance and, furthermore, it is found that the deciduomata are very small in cases in which the incision had been made near the tubal end of the uterus, inasmuch as such an incision renders possible the exposure of only a very small area of the uterine mucosa.

13. Of the three factors concerned in the development of the maternal placenta, the sensitizing substance of the corpus luteum shows the highest degree of specificity, while the mechanical factor is the least specific, inasmuch as its place can be taken by an apparently totally different process, namely, the insertion of the ovum.

It is, therefore, not to be wondered at that even the stimuli always present in normal tissue life have some effect in exciting certain reactions in a uterine mucosa which has previously been sensitized by the specific substance of the corpus luteum. In experiments in which I prevented the ova from entering the uterine cavity after ovulation I found, indeed, that even without a preceding incision at a certain period after ovulation, when the uterine mucosa has been sensitized, certain predecidual changes take place normally and rhythmically, leading in the guinea-pig to the appearance of many mitoses and to a myxomatous condition in the connective tissue, and in the rabbit to an amitotic division of the epithelial nuclei.

Here, again, a quantitative relation is seen between exciting conditions and the extent of the changes produced. The normal stimuli of tissue life are quantitatively very much inferior to the experimental incisions and to the insertion of the ovum and lead, therefore, only to the beginning of placental changes.

14. The experimental facts just mentioned may explain the difference in the structure of uterine and tubal mucosa in the guinea-pig. The former is very rich, the latter is very poor in cells. Correspondingly we find that the uterine mucosa can be sensitized by the corpus luteum substance, while, as we shall see later, the tubal mucosa in the guinea-pig can not be sensitized.

This process of sensitizing enables the connective tissue of the uterine mucosa to proliferate periodically, to be more or less in a rhythmic condition of growth, while the tubal connective tissue is resting. After cessation of sexual activity the uterine mucosa must become atrophic, being no longer under the influence of the sensitizing substance of the corpus luteum.

These observations enable us, therefore, to correlate structural differences between the mucosa of the uterus and the Fallopian tube with certain dynamic biochemical differences, namely, difference in the ability of certain tissues to combine with the sensitizing substance provided by the corpus luteum.

15. The substance which is produced in the corpus luteum and which sensitizes the mucosa of the uterus has a specific affinity to the uterine tissue. In a number of experiments I made incisions into the peritoneal wall, into the ovaries, into the Fallopian tubes of the guinea-pig, into the subcutaneous tissue, and I transplanted skin in animals at the critical period, but in no case did I find any unusual reaction in these tissues, none of these tissues or organs having become sensitized.

This is especially noteworthy if we consider that apparently the ordinary connective tissue is the same everywhere in the body.

This specific affinity of a certain chemical substance could be explained, however, if we assume that the identity of the different connective tissues of the body does really not exist, or, as an alternative, we could refer the specificity, not to the connective tissue, but to the surrounding epithelium, of which we know that it differs in structure and, therefore, in metabolism from other epithelial structures. The connective tissue would then receive the stimulus only through the intermediate action of some other cells.

16. This specificity which is established experimentally clears up another related problem.

On the basis of many experiments I can state that in the guinea-pig it is impossible to produce at will an extrauterine tubal or abdominal pregnancy. The ovum which after fertilization is prevented from attaching itself to the uterine wall perishes without forming an embryo.

We are now able to state why an extrauterine pregnancy is impossible in the guinea-pig: Neither the tube nor the peritoneal lining nor the ovarian tissues are able to produce the maternal part of the placenta in response to the stimulus of the ovum touching the uterus, and without a maternal placenta the egg is unable to develop.

In man we occasionally do find such a response in the case of tubal pregnancy; here the specificity in the fixation of the corpus luteum substance is less marked than in the guinea-pig.

17. I have already stated in a former communication that it is possible to obtain growth of the decidua in a piece of uterine tissue which is excised and transplanted into the subcutaneous tissue of the same animal. This proves that the formation of the placenta does not stand under the regulative influence of the central nervous system, and probably not of local nerves, it being very unlikely that such peripheral nerves and ganglia cells would functionate after transplantation of a small segment of the uterus. In the large majority of my experiments the pieces were transplanted several days after ovulation; therefore, at a time when the sensitizing of the uterine tissue in all probability had already taken place. Such experiments, therefore, do not prove that the sensitizing takes place through a chemical agency carried to the uterus through the circulation and not through the nerves. In two cases, however, in which the transplantation was done within the first twenty hours after ovulation and in which, therefore, in all probability the uterine tissue has not yet been sensitized before transplantation small deciduomatous areas formed in the transplanted uterus. This indicates that the sensitizing substance is carried from the corpus luteum to the uterus through the circulation and that it is not transmitted through the nerves.

18. But is it possible to obtain a decidua in the transplanted uterus only after transplantation into the same animal? I have so far not been able to obtain the formation of a well-developed decidua after transplantation into a male guinea-pig. In a large series of experiments I exchanged the uteri in animals which were known to be at the same period after ovulation, in animals therefore, in both of which the sensitizing substance was present. Notwithstanding this equality of conditions there was a notable difference in the results. After transplantation into the same female the number of deciduas formed in the various experiments was greater and the size of the deciduas was larger in the positive cases. These experiments I intend to extend still further. But at present it is very likely that the body fluids are different in the different individuals of the same species and that this difference is of importance for the cell growth and that at least some tissues show a specific adaptation to their individual body fluids and that such an adaptation becomes especially apparent in certain conditions of unusual functional activity. This result is a further confirmation of my former findings, according to which certain tumor tissues remain alive after transplantation into the individual in which they originated, but die after transplantation into other individuals of the same species.

19. We see that in the transplanted uterus a decidua can be produced under the conditions valid in the case of the untransplanted uterus.

Where and from what kind of cells does the decidua form in the transplanted uterus? Do the invading connective-tissue cells of the host tissue become converted into decidua in contact with the uterine structures? In examining the uterus at various stages after transplantation, it becomes apparent that not only the transplanted glands remain alive, but also the connective-tissue cells in the neighborhood of the glands, and precisely at this place, the deciduomata are formed; we have therefore, sufficient reason for believing that the connective tissue of the transplanted tissue of the host gives origin to the deciduomata—just as in tumor transplantation, sarcoma and carcinomata arise from transplanted cells and a new infection of the host cells does usually not take place.

20. It will not be necessary here to discuss the bearing which these experiments have on the analysis of tissue and of tumor growth, as I have done this at some previous occasions. It may suffice to state that I have here been able to demonstrate the interaction of various sets of factors which all have to participate in a quantitatively determined way at stated periods in order to produce a growth which differs from the ordinary regenerative and bears some resemblance to tumor growth.

4109 Pine Street.

ABSTRACT OF DISCUSSION

Dr. Maximilian Herzog, Chicago: The work done by Dr. Loeb is interesting, and it is probable that it will give us an important clue to some of the fundamental principles underlying placenta formation. Those pathologists who have had a chance to study very early placenta formation in some of the lower animals and in the human species have been struck by the fact that it presents the paradigm of two important pathologic processes—viz., of malignant tumor formation and of inflammation. The former is represented by the trophoblast, which invades the maternal tissues in the same manner as a malignant tumor invades the tissues in which it grows. The latter is represented by the decidua, which gives us the picture of a tissue in profound acute inflammation. It has been my good fortune to obtain a specimen of a very early human ovum *in situ*, and I first presented a preliminary report of it to the Seventh International Congress of Zoology, held in August, 1907, in Boston. In my preliminary report I stated these facts and gave it as my opinion that some of the changes produced in the maternal tissues are not due merely to the mechanical insult of the penetrating ovum, but to an enzyme secreted by the trophoblast. Dr. Loeb believes that the changes, as he has produced them experimentally in animals, are due to the trauma plus a sensitizing substance secreted by the corpus luteum. If I understand him correctly, the corpus luteum in guinea-pigs is formed by the zona granulosa. This is not true in human beings, in which it is formed partly from the theca interna and partly from the theca externa. I believe that the hypothetical enzyme that causes the decidual change in the maternal tissues is furnished by the trophoblast. We find some support for this belief in the observations first made by Bonnet and Marchand, that the syncytium surrounding the trophoblast has a complete lining of cilia. Such a lining is ordinarily found in secretory epithelial cells.

One word as to the terminology: I believe that it is not correct to speak of these decidual formations as deciduomata and to classify them as tumors, because I do not think that they are true tumors, and do not suppose that Dr. Loeb considers them as such. From what I have learned and seen of Dr. Loeb's investigations I believe that these experimental decidual masses should be looked upon as inflammatory hyperplasias. We know from human pathology that there is hardly any structure in the body in which inflammatory hyperplasias are more common than in the uterine mucosa. It seems to me that in the case of Dr. Loeb's experiments in guinea-pigs we have a sensitizing of the mucosa by an enzyme; and the traumatic insult, in combination with the former, causes an inflammatory hyperplasia.

Dr. H. Gideon Wells, Chicago: The development of the placenta has peculiar interest from the general standpoint of biologic chemistry, from the fact that we have developed in a comparatively short space of time an organ equipped for carrying on complex metabolic processes. The work of Bergell has shown that the placenta is more than an organ for regulating diffusion of substances to and from the offspring—that it is intended for carrying on a considerable portion of the metabolism of the growing fetus. I have had occasion to study the purin metabolism of the human placenta, and have found that the placenta is endowed with the same enzymes common to other tissues of the adult human being; and also that among the purins there is a large proportion of hypoxanthin, whose presence is an indication of a high degree of metabolic activity going on in the tissues. Those tissues not actively carrying on nuclear metabolism have most of the purins in the form of adenin and guanin. The active tissues have large quantities of hypoxanthin, and I find that the amount in the human placenta is quite large in proportion to the other purins.

Dr. M. J. Rosenau, Washington, D. C.: How does Dr. Loeb account for the fact that these placental formations do not occur in human beings following surgical operations, which certainly occur in certain cases at favorable times following corpus luteum formation.

Dr. Leo Loeb, Philadelphia: Dr Herzog seems to assume that the corpus luteum in man originates through proliferation of the cells of the theca interna and externa. I do not believe, however, that he will be able to produce sufficient evidence for his conception. The difficulty of the corpus luteum problem is that only in a few animals has a good study of the development been made. Sobotta showed that if we take animals the age of whose corpus luteum is known it can be demonstrated that it is derived, not from the theca interna or externa, but almost entirely from the granulosa. He found it in the rabbit and white mouse, and I found it in the guinea-pig. Until an equally thorough investigation shall have been made in man we can assume that the origin of the corpus luteum in man is the same as in animals.

As to the enzymes of the trophoblast, there is great likelihood that it contains some proteolytic and, perhaps, some other enzymes. No definite study, so far as I know, has been made of it, however. That the enzymes of the trophoblast have any formative action on the placenta, however, has not been shown; and there is practically no evidence in favor of this. In the course of my investigations I found that the ovum acts in a way similar to incisions in the uterine wall. That the trophoblast represents the stimulating part of the developing ovum is quite improbable, inasmuch as under the influence of the ovum the decidua begins to form before the trophoblast has been formed. Without the sensitizing action of the corpus luteum the ovum is, in the large majority of cases (probably in all cases), unable to cause a production of a maternal placenta; after early extirpation of the corpora lutea the ovum is no longer able to call forth the development of a well formed decidua in almost all cases, as I have shown experimentally.

I would not advise classing these deciduomata as inflammatory hyperplasias, as Dr. Herzog recommends; because if we do that we shall have to call the maternal placenta an inflammatory hyperplasia, and I do not see any advantage in doing that. To some extent I sympathize with Thoma, who wanted to do away entirely with the term inflammation, as being confusing. In this case the term inflammatory hyperplasia would certainly be actively out of place, as there is no inflammation in a properly conducted experiment. As to the relations of these experimentally produced new formations to tumors, I can in the main refer to my former articles.

In answer to the question of Dr. Rosenau as to why deciduomata are not found in patients after surgical operations I would say that I have little doubt that if pathologic examinations were made at the proper time changes characteristic for human maternal placenta would be found.

Physical Exercise in Schools.—In the public schools there should be not only systematic physical exercises, which should be given in close connection with the instruction in physiology and hygiene, but there should also be the largest possible amount of muscular activity in connection with all studies.—W. E. Garrison, in *Hygiene and Physical Education.*

CANCER CYSTS OF THE BREAST AND THEIR RELATION TO NON-MALIGNANT CYSTS *

JOSEPH C. BLOODGOOD, M.D.
BALTIMORE

New problems and new responsibilities accompany all surgical diseases when they appear for treatment at an earlier stage of the disease than hitherto. Accumulated experience demonstrates that surgical interference of any kind promises better immediate and ultimate results when this procedure is instituted at a period in which the diagnosis is most difficult. This is especially true of tumors and is well exemplified in tumors of the breast.

Pathologists are less interested in gross and cellular pathology to-day than formerly, because investigations as to the etiology of disease along the lines of gross and cellular pathology have been about exhausted or have reached their limit of evident usefulness. Pathologists, therefore, are more and more interested in experimental pathology and physiologic chemistry. Surgeons, I am convinced, will become more and more interested in the gross and cellular pathology of the diseases that they are called on to treat, because this knowledge is of practical importance. It does not seem a good plan to have one set of men make the diagnosis and another institute the treatment.

I can exemplify these new problems and responsibilities very clearly by a discussion of cysts of the breast. If every tumor of the breast was seen by the surgeon within a few hours or days after it was first felt, very rarely would that surgeon be able to make the diagnosis as to the nature of the tumor from the examination. The diagnosis would, therefore, have to be made by exposing the tumor so that its gross or cellular features (from a rapid frozen section) could be studied.

It appears to me that the responsibility of the surgeon is very clear: he should be his own pathologist. But I am confident that for a number of years in many clinics surgeons will still desire to have pathologists present at the operation to make for them the diagnosis from the frozen section.

These remarks, therefore, in regard to cysts of the breast are directed to surgeons who wish to make their own pathologic diagnosis, or to pathologists who are called on to assist surgeons in the diagnosis of surgical diseases.

I wish, however, to repeat that clinicians will find it incumbent on them to keep pace with that knowledge of physiology and pathology which practical surgery and medicine require for diagnosis and treatment.

Among surgeons there are various views in regard to the method of making a diagnosis when it is impossible or doubtful clinically. Some cut down on the tumor and make the diagnosis from the gross appearances; others, in addition to this, cut out a small piece for an immediate frozen section. It is this method that I prefer—the direct exploration of the tumor. After a time a surgeon can train himself to dispense with immediate frozen sections except in rare instances. In my experience, after one has had a sufficient training, the diagnosis from the gross appearance is easier and undoubtedly quicker and, in many cases, more certain than from a *rapid* frozen section.

Other surgeons prefer to cut the tumor out locally and then cut into it and make a frozen section. This method, it seems to me, has greater dangers of dissemination than the former. But I have had no experience with it, and, therefore, can not speak authoritatively. In my experience, direct exploration of the tumor, if followed at once by the indicated operation, has practically no dangers, even though the disease be malignant. One can, of course, recognize the advantages of this method if the lesion is benign.

Other surgeons expose the lesion, cut out a piece, or cut out the tumor, close the wound and then wait a day or two for a careful microscopic diagnosis based on a carefully prepared section. This method, from the standpoint of the pathologist, is undoubtedly the best, but from the standpoint of the patient and the surgeon the worst. I have had sufficient experience with the results of this method, from tumors and tissues sent to me for diagnosis, to know that in the large majority of cases it has proved fatal in tumors in which, from an experience based on the other methods, one would regard a cure as probable.

With the evidence which I have been able to accumulate I feel that there is no doubt as to which is the best method. The diseased tissue must be exposed directly and the diagnosis made at once, either from the gross appearance or from the rapid frozen section.

For this reason I would urge pathologists who are associated with surgical clinics to be present at the operations, so that they may see the gross appearance of the diseased tissue as well as the histology from the frozen section. And, in addition to this, before they make a diagnosis, they will find that knowledge of the clinical history will prove of value.

The responsibility of a diagnosis in many of these cases is a very great one: life often depends on it; unnecessary mutilation may be saved by it. From my own experience I am convinced that the careful association, in rapid sequence, of the clinical history, examination of the gross appearance and frozen section will be more valuable in the diagnosis than any one of these alone. When the surgeon is his own pathologist he has all the evidence; the pathologist, unfortunately, asks for and gets the cellular picture alone.

It is my opinion that the pathologist will be more helpful to the surgeon if he would but study the clinical and the gross as well as the histologic aspects of the surgical lesions that he is called on to diagnose.

A diagnosis at an operation is an entirely different thing from the diagnosis at an autopsy. The knowledge that a diagnosis can be made at an operation in the majority of cases should be disseminated, so that a surgeon will be discouraged from assuming the responsibility of operating on such lesions unless he is prepared himself to make the diagnosis, or unless he has connected with his clinic a pathologist who can.

Of breast tumors in the surgical clinic of Professor Halsted of the Johns Hopkins Hospital, 31.5 per cent. were benign. Among these benign lesions 25 per cent. were simple cysts, 5 per cent. papillomatous cysts, and 1 per cent. galactocele, or a cyst due to chronic mastitis. Over 30 per cent., therefor, of benign lesions are cystic. With but few exceptions, cysts appear during the cancer age. Among the carcinomas, about 25 per cent. are cysts, about equally divided between the cancer cysts and the malignant papillomatous cysts.

To about every hundred benign cysts there are about twenty-five malignant cysts. Therefore, if malignancy is not recognized in almost 20 per cent. of cases of cyst, malignant disease will be improperly treated. If the cancer operation is performed in every case of cyst four women will be unnecessarily mutilated in every five operations.

---

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixtieth Annual Session, at Atlantic City, June, 1909.

This lesion—a cyst of the breast—exemplifies the new problem and the new responsibility which I brought out in the beginning of this paper.

CANCER CYSTS

I have notes on fourteen cases in the surgical pathologic laboratory. In seven (50 per cent.) the tumor was clinically benign, and the diagnosis had to be made, when the cyst was opened, from the contents, or from the character of the wall, or from a frozen section of the wall. In five of these seven cases the diagnosis was not made until a stained section had been studied in the laboratory.

The study of these cases allows one to give a gross description which is so characteristic that one familiar with this picture should not make a mistake.

In six of the cases the contents of the cyst has been *hemorrhagic*. Up to the present time I have never observed blood in a smooth-walled cyst, except when associated with carcinoma in the wall. The benign papillomatous cyst may have hemorrhagic contents, but when there is no papilloma to explain the presence of blood the cyst should be treated as a carcinoma. In the remaining eight cases the contents, although not hemorrhagic, have been so granular, up to almost solid grumous material, that one could be certain that there must be a malignant epithelial tumor in the wall.

The diagnosis of a cancer cyst can, therefore, be made from the contents. In many of these cancer cysts one can see or feel with the knife or finger the carcinoma in the wall. In some cases the carcinoma is only a small nodule situated in one portion of the wall of the cyst, while in other cases it is found diffuse in the entire wall. As I am interested in presenting chiefly the picture which will allow a diagnosis, I shall not discuss the etiology of cancer cysts. When the wall of the malignant cyst has been moderately smooth and it has been difficult to recognize in the only moderately thickened wall any evidence of carcinoma, the contents have always been hemorrhagic.

In making the diagnosis of a cancer cyst from the frozen section the surgeon must remember that he might remove a piece from the non-cancerous area. In another possibility it might be difficult, except to one with considerable experience, to differentiate the cancer cyst from certain changes in the wall of a perfectly benign cyst which will be discussed later. There are chiefly two—an area of chronic interstitial mastitis in the wall and a small adenocystic area of senile parenchymatous hypertrophy.[1] I will discuss this more in detail under simple cysts.

The point that I wish to illustrate and to emphasize is that I believe that the diagnosis of a cancer cyst can be made with greater certainty from the gross appearance of the contents than from a rapidly frozen section of the wall.

The most recent case of cancer cyst which I have observed was that of a patient operated on before the Clinical Society of Surgery at its recent meeting in Baltimore (April, 1909). I did not feel justified in performing the cancer operation in this case. The tumor, of two weeks' duration in a woman of 43, was evidently a cyst, but the palpation of the tissue outside the wall of the cyst made me feel that I was dealing with a rare cancer cyst, because it reminded me of the first cancer cyst which I had observed with Dr. Halsted. In exploring this cyst no change whatever was found in the fat; the exposed cyst wall, before it was incised, had the smoothness, thinness and bluish color of a benign cyst. But when I opened this cyst the non-hemorrhagic contents were so granular that I was convinced of its malignant nature. On putting my finger into the cyst I could feel a little cancerous nodule in the opposite wall. In this case a frozen section of the wall through which I opened the cyst would have shown no carcinoma. To get a piece of tissue from the part of the wall that felt carcinomatous would have been difficult, and in my opinion dangerous, because in cutting through at this point one would have opened into the space between the breast and the pectoral muscle. The complete operation for carcinoma was therefore performed without obtaining a piece for frozen section.

BENIGN SIMPLE CYSTS

The cancer cyst must be differentiated from the benign simple cyst, and this differentiation (to repeat) is of great importance, because for the benign cyst in many cases excision of the cyst alone is sufficient, or, at the most, excision of the breast. It is rather interesting that among seven of the cancer cysts, clinically benign, in five the disease was not recognized at the first operation and the cyst only was removed. On the other hand, in about 100 cases of simple cyst the cancer operation has been performed in 16. Sixteen women, therefore, were unnecessarily mutilated, while in five among the cancer cysts the probabilities of a permanent cure were very much reduced by an operation in two stages. In fact, only one of these five patients was cured.

I have discussed elsewhere with considerable detail a disease of the breast which I have called senile parenchymatous hypertrophy. This lesion presents itself in two forms: with one or more cysts, as first described by Billroth as chronic cystic mastitis, and an area of hypertrophy in which large cysts do not develop; this second form has been called Schimmelbusch's or Réclus's disease. I have ventured to designate it as the adenocystic type of the aforesaid hypertrophy.

The type in which one or more cysts develop must be distinguished from the cancer cysts, while the adenocystic type must be differentiated from adenocarcinoma. This latter differentiation requires greater experience, as it is much more difficult both in the gross and frozen section.

This disease, especially the type in which cyst formations predominate, is, in my experience, a distinctly benign lesion. Among 106 cases of which I have records carcinoma has never been observed, and among about 500 carcinomas of the breast in only two instances have I observed cancer and a simple cyst present in the same breast. Among these 106 cases in two instances I have noted carcinoma in the opposite breast.

The disease, therefore, can and should be treated conservatively by those who are able, with absolute certainty, to make the differential diagnosis. If the surgeon on whom the responsibility for the operation rests has any doubt I would distinctly urge that the cancer operation be performed.

The conclusion that this hypertrophy is a benign lesion is based on the following observations:

In six cases no operation was performed. In two there was but a single palpable tumor, in three there were multiple tumors in one breast, and in one there were multiple tumors in both breasts. These six cases have been followed, and in four, in which more than three years have passed since the examination, the tumors have disappeared. In one case it is thirteen years since the first observation of the patient.

---

[1] Bloodgood: Surg., Gynec. and Obst., 1906, iii, 721.

2. Bloodgood: Surg., Gynec. and Obst., 1906, iii, 721; Am. Jour. Med. Sc., 1908, cxxxiv, 157; Kelly and Noble's Gynecology and Abdominal Surgery, ii, 180.

In twenty-seven cases the cyst and a zone of breast tissue were removed. In all but three there was, clinically, but one tumor, and this single tumor was explored for diagnosis. In three cases the diagnosis was rather positive, because there were multiple tumors in both breasts, and one or more were excised because of discomfort.

In the three patients with multiple tumors I had the opportunity to observe the ultimate result. One, a patient of my own, was operated on twelve years ago; within three years the shot-like nodules disappeared, and they have not returned. In the second case it is six years since the operation, and I am informed that the patient has had no further trouble. The third is a recent case.

Among the twenty-four patients who presented, clinically, but a single tumor and from whom at operation only the cyst and a zone of breast tissue was removed, there has developed not a single example of carcinoma, and at the present time but two have developed other cysts. The first was a patient of my own, operated on now almost ten years ago, for a cyst in the upper and outer quadrant of the left breast; five years later she returned with a similar cyst in the upper and inner quadrant of the same breast; the cyst was removed. To-day both breasts are normal. The second case is a recent one, and I have just been informed that a tumor has developed in the other breast.

I am of the opinion that these observations over a period of now more than ten years in carefully studied cases justify the conclusion that conservative means can be employed without risk for benign simple cysts of the breast, provided the surgeon or pathologist is able to make the diagnosis from a cancer cyst at the exploratory incision.

In studying these twenty-seven cases in which the cyst only was removed I find that in every instance the contents of the cyst were either clear or slightly cloudy serum—never hemorrhagic, granular or grumous.

The cyst wall has always been smooth and not thick. In the breast tissue surrounding the cyst and cut through during the excision of the cyst dilated ducts filled with grumous pastille material have been found in six cases, and in these, in addition, there have been a few minute cysts of the size of the head of a white pin or a little larger.

Among the single tumors definite areas of the adenocystic type of the hypertrophy have been present in but two instances. When this has been present to any extent it has been my rule to excise the breast. Among the three cases in which one or two of the multiple tumors were removed, this adenocystic type was present in two.

The observations just discussed demonstrate that for the simple cyst situated in a breast in which the senile parenchymatous hypertrophy has not reached the adenocystic type, conservative measures are justifiable. When the adenocystic areas are present to considerable extent, I have as yet no evidence to offer that it is justifiable not to remove the breast, but I am of the opinion that further observations will allow us to select cases for conservative treatment even in this group.

In the remaining cases either the entire breast was removed or the cancer operation performed. These cases, therefore, allow one to study the opposite or remaining breast only, but can not be used as evidence for or against the conservative treatment of this disease.

In this group, however, we are brought in contact with those cases in which the diagnosis of carcinoma has been looked on as sufficiently indefinite to justify the complete operation for carcinoma.

Among 50 cases in which the breast contained a simple cyst the cancer operation has been performed 12 times, that is, in 24 per cent. of the cases, while among 15 cases of the hypertrophy without cyst formation the cancer operation has been performed 5 times; that is, in about 33 per cent.

Among the twelve cases of cyst treated as cancer, in six the operation was performed without an exploratory incision. In only one of these cases was there a definite clinical sign of cancer. This was a patient of Finney, and the nipple was retracted. In the other five cases the palpation of the tumor gave the surgeon the impression that it was carcinoma.

It requires a great deal of experience to diagnose cancer of the breast from palpation of the tumor alone. When this sign is present and no others, I am of the opinion that an exploratory incision should be made. In the six cases in which the cancer operation was performed without exploratory incision there would have been no difficulty in making the diagnosis of a benign simple cyst if the tumor had been explored.

Of the six cases which were explored, in one there was a thick-walled cyst; in another, two dilated ducts from which pastille contents could be expressed, and in a third case a small area of the adenocystic type of the hypertrophy in the wall. In these three cases the gross appearance and the frozen section would give rise to some difficulty, but I believe that after moderate experience such cases will be recognized. The mistake has never been repeated in Dr. Halsted's clinic. In the remaining three cases there was no reason for the mistaken diagnosis. The cysts were present in a rather senile, fibrous breast. These patients were operated on by surgeons who had had very little experience, and they deemed it wiser to perform the cancer operation, as they were in doubt.

I have gone over this point with considerable care and before writing the above have carefully studied each individual case, with the conclusion that the differential diagnosis between a cancer cyst and a simple cyst, now that we have the evidence presented, should not be a difficult one.

Now, when we come to differentiate the benign adenocystic type of the hypertrophy from adenocarcinoma, we have a more difficult problem. But I wish to emphasize this point: If in all such cases the treatment is for cancer, there would be relatively but a few patients on whom the cancer operation would be performed unnecessarily. But in the larger group, the cysts, the benign cysts so far outnumber the cancer cysts that it is distinctly worth while educating oneself to make the differential diagnosis.

In the senile parenchymatous hypertrophy without the large cyst formation, which is also known as Schimmelbusch's disease, and which differs from the cystic adenoma of the breast only in the fact that it is not encapsulated, the differentiation from carcinoma, clinically, in the gross, and in the frozen section, and even in the better stained section, may be very difficult, in inverse proportion to one's experience. I have examples of a mistaken diagnosis in each group. Clinically, it may simulate carcinoma, because the zone is hard and nodular; at the exploratory incision the little cysts filled with proliferating epithelial cells in a comparatively fair amount of stroma suggest adenocarcinoma. I shall have to leave to a larger contribution to be published later the details of this differential diagnosis. It can be made with certainty and safety to the patient.

PAPILLOMATOUS CYSTS

I find I have tissues and records of thirteen cases of malignant papillary cysts and twenty cases of distinctly benign cysts containing an intracystic papilloma. The diagnosis in the malignant intracystic papilloma could be made in all but three cases clinically. In many of these cases there was a long history of tumor and of discharge of blood from the nipple, but this was not present in all the cases.

The clinical diagnosis could be made from the retraction of the nipple or some involvement of the skin. For this reason an exploratory incision was not necessary. But the examination of these breasts after the operation revealed a pathologic picture entirely different from the benign cyst. There was no longer a papilloma in the wall, but a soft fungous growth, like a medullary carcinoma. One could distinguish, then, the malignant papilloma from the benign without difficulty. None of these cysts contained pure blood, but a grumous, granular material, sometimes hemorrhagic.

In three cases the cysts were clinically benign, but on account of the character of the contents of the cysts and the appearance of the tumor projecting from the wall a diagnosis of a malignant cyst could easily be made. In this group of thirteen cases there was but a single mistake made, but in this—an outside case—the breast had been removed. If the surgeon had made an exploratory incision there would have been no difficulty whatever in making the diagnosis. In this case there was a local recurrence eleven months after the removal of the breast.

Among the twenty benign cases, in six—about 30 per cent.—the tumor was treated on the diagnosis of carcinoma. In four of these cases an infection of the benign cyst produced changes in the skin so closely suggesting a malignant cyst that the operation for carcinoma was performed without an exploratory incision; one of these was a case of my own. In the remaining two cases the surgeon at the exploratory incision, in addition to a papillomatous cyst, found, in the wall of this cyst, a small area of senile parenchymatous hypertrophy, and interpreted it as carcinoma. That is, we have the same difficulty here as was experienced in the simple cysts with a similar minute cystic area in the wall.

In all of these cases of benign papillomatous cysts the contents of the cyst have been clear or hemorrhagic, never grumous or granular. The typical appearance of the benign papilloma (that of a raspberry or strawberry) was preserved; now and then the papilloma filled the entire cyst. That we were correct in our diagnoses in this group is confirmed by the study of the ultimate results. Every patient is apparently well to-day. The glands in the six cases in which the cancer operation was performed showed no metastases. In three cases only the tumor was removed; in the remaining—not treated as carcinoma—the breast. None of the cases were bilateral. The age of the onset varied from thirty to sixty-four; the duration of the tumor from three weeks to fifteen years. In over 75 per cent. of the cases there was discharge from the nipple, usually hemorrhagic. In one the cyst involved a male breast.[3]

I trust that I have shown by this summary of cysts of the breast that the correct diagnosis in the early cases must rest on the gross and microscopic pathology. If patients seek the advice of surgeons earlier, the surgeon will less frequently be able to use his art of clinical diagnosis, but must employ his own pathologic diagnostic abilities, and, if this is not at hand, he will require the services of the pathologist of his clinic.

904 North Charles Street.

ABSTRACT OF DISCUSSION

Dr. William C. McCarty, Rochester, Minn: There are types of malignancy in papillary cysts of the breast, i. e., malignant change in the epithelium of the papillomata and change in the breast tissue surrounding the cyst. These perversions in the cells may be best discovered and studied at the time of operation by making frozen sections and staining them with Unna's polychrome methylene blue. Such sections can be made in from fifty seconds to two minutes, and are not only as good as paraffin and celloidin sections, but are better and more accurate, and may be photographed with better results. The importance of such early diagnosis may be seen from the fact that about 80 per cent of the tumors of the breast are malignant and experience has taught us that about half of the remaining 20 per cent would become milignant if left alone. The standard usually taken by pathologists that the cells must dip beneath the basement membrane before being considered malignant is, in my opinion, too conservative. This has been especially true in papillary growths of the bladder, specimens of which removed through the cystoscope have been reported malignant purely on cell studies. These specimens were proved to be malignant after resection by the fact that the cells in the base had dipped below the basement membrane.

Dr. Henry S. Wieder, Philadelphia: I am in the habit of considering the whole condition of cystic disease of the breast as only a part of general involution. In my experience it seems that the cystic variety is not so common as the more important proliferative variety in which, according to Dr. Warren, is more frequently found carcinomatous change. In the true cystic variety one rarely finds carcinoma associated, but one does find it in a high percentage of cases of the proliferative type. I believe that a careful study of this disease is the secret of early diagnosis of carcinoma. All cases should be studied thoroughly to discover whether they have undergone adenomatous involution and whether this is associated with carcinoma.

Dr. J. C. Bloodgood, Baltimore: Most of these photomicrographs were taken from frozen sections. It is to be remembered that in the beginning my training was distinctly that of a surgeon and that I attempted to educate myself to recognize disease in the gross. The opportunities for this were first afforded by the great number of tumors which came to the clinic in which there was no difficulty in making a clinical diagnosis. In those earlier days we did not often see carcinoma and other malignant tumors of the breast and elsewhere in that period in which a clinical diagnosis could not be made; but when this did happen, it was found that the disease exposed at the exploratory incision during the operation did not differ at all from the many that had been studied carefully in the laboratory after operation. I would like to state here that I found Dr. Halsted using this method of diagnosis when I came to his clinic in 1892. Practically, we never depend on frozen sections. During the past five or six years we have been making frozen sections in order to show the students within a few minutes the relation between the gross and microscopic picture. Dr. Lambert has developed the technic of frozen sections to such a point that for practical purposes they are almost as good as more carefully prepared sections. But the frozen section made within a few minutes is never quite so clear as one made from tissues which have been hardened in formalin.

---

[3] Peck: Ann. of Surg., September, 1903, xxxviii, 450.

I am aware that few surgeons or pathologists will agree with me that it is easier to make the diagnosis from the gross appearance. I will admit, however, that the two together are better than either, but if one must depend on only one of the two, with my training, I should prefer the gross. My histologic conception of malignant disease, for example, carcinoma, is based on a long observation of the combination of the clinical, gross and microscopic appearances. Up to the present, for every histologic picture that has been considered malignant I have observed at least one example of metastasis and death from cancer. And for every picture considered benign, further clinical observation has confirmed the diagnosis. Dr. Welch has often remarked to me that the surgeon who studies his cases pathologically and keeps track of the ultimate results has a much better opportunity to become conversant with the relative grades of malignancy, for the pathologist seldom has an opportunity to keep track of the ultimate results.

HEMOLYSIS IN THE DIAGNOSIS OF MALIGNANT NEOPLASMS *

O. P. JOHNSTONE, M.D., AND C. H. CANNING, M.D.
PITTSBURG, PA.

The importance of the early diagnosis of malignant neoplasms and tuberculosis seems a sufficient reason for reporting the observations in the following cases.

The aim has been to study the reaction in as wide a series of various conditions and diseases as possible, and thus to throw as much light as possible on the value of the reaction from a diagnostic standpoint rather than merely to duplicate the work already done with reference to carcinoma and tuberculosis.

With reference to the reversed hemolysis in tuberculosis, the aim has been to study the reaction in early cases, and in those with small localized or latent lesions with slight or no positive clinical symptoms or signs, but giving a positive tuberculin reaction.

Table 1 is a list of the findings in such tuberculous cases studied, the hemolytic reaction being negative in the large proportion in which the lesions were latent or small in extent with no definite clinical symptoms, and reversed when the lesion was extensive or decidedly active in character.

One such case, that of a patient with apparent involvement of the mediastinal glands but with no definite symptoms other than an occasional temperature of 0.5 degrees at times, was studied both before and during tuberculin treatment. Before treatment there was a tendency toward an unstable condition of the red corpuscles with reference to normal serums, but not sufficient to produce a typical reversed reaction in any examination, a number of examinations being made both before and during the treatment. After three or four weeks' treatment with increasing doses of tuberculin, the corpuscles become more stable, and in all subsequent examinations reacted exactly as normal corpuscles. No patients giving a typical reversed reaction were treated with tuberculin and the blood examined subsequently, so this single case may or may not be significant, but the behavior of the corpuscles toward normal serums after the treatment was well under way was certainly very suggestive.

Thus only the advanced or decidedly active cases gave reversed hemolysis, the others being negative. With the exception of the two pulmonary cases and the case of tuberculosis of the hand, in which the tuberculin test was not made, all gave a positive tuberculin reaction. The pulmonary case failing to give the reversed hemolysis was that of a patient 70 years of age. The clinical diagnosis was carcinoma of the stomach, and a gastroenterostomy was performed. The case came to autopsy one week later, when duodenal ulcer was found. Old tuberculous cavities the size of a goose-egg and caseous nodules were present in the lungs.

TABLE 1.—TUBERCULOUS CASES

Character of Cases.	No. Cases.	Reversed Reaction.	Negative Reaction.
Tuberculous knee	2	1	1
Tuberculous hip	2	..	2
Tuberculous spine, advanced	1	1	..
Tuberculous lungs, advanced	2	1	1
Tuberculous peritonitis	4	4	..
Tuberculosis of bladder	1	..	1
Tuberculosis of hand	1	..	1
Tuberculosis, glandular or pulmonary, slight or no clinical symptoms	30	..	30

The degree of hemolysis occurring varied considerably in different cases, being more marked as a rule in the larger and softer tumors and those showing considerable necrosis, and less in the smaller and harder varieties. Several of the cases above classified as negative showed slight hemolysis late; i. e., after forty-eight to seventy-two hours. The two cases of carcinoma of the rectum giving a negative reaction were not examined microscopically, so the clinical diagnosis was not verified in these two.

TABLE 2.—CARCINOMA CASES

Character of Cases.	No. Cases.	Positive Reaction.	Negative Reaction.
Carcinoma of stomach	16	15	1
Carcinoma of breast	11	9	2
Carcinoma of uterus	7	6	1
Carcinoma of rectum	3	1	2
Carcinoma, others	6	6	0

The hemolysis was not as marked in the cases of sarcoma studied as in many of the carcinoma cases, but with the exception of Case 6 all were of small or moderate size. One other patient was operated on and Coley's fluid given for three months following the operation. Six months after the operation the blood was examined, the reaction being negative. There has been no recurrence, one year after operation. Patient 1 was examined several times during the use of Coley's fluid, the reaction being marked at first and becoming less pronounced with each following examination. Coley's fluid was given daily for about seven months, then twice a week, and again given daily for two weeks prior to the final examination. This final examination showed but a faint trace of hemolysis. The hemolysis in the other cases of sarcoma treated with Coley's fluid appeared to increase slightly with the use of the mixed vaccine, the examination in these cases being made in the early weeks of the vaccine treatment.

TABLE 3.—SARCOMA CASES

No. of case.	Character of Cases.	Reaction.
1	Sarcoma of skin; incompletely removed	pos.
2	Osteosarcoma of knee	pos. sl.
3	Spindle-celled sarcoma; ankle; small	pos. sl.
4	Spindle-celled sarcoma; neck and axilla; half-orange size	pos.
5	Giant-celled sarcoma of knee; small	pos. sl.
6	Spindle-celled sarcoma; abdominal cavity; large mass	pos.
7	Small round-celled sarcoma; neck; small	pos.
8	Osteosarcoma; thigh; removed; metastasis in lung	pos. sl.
9	Small round-celled sarcoma; groin; small	pos.

Two cases of endothelioma were examined, hemolysis occurring in each. One was an endothelioma of the meninges, the other of the peritoneal cavity.

No benign tumors showed hemolysis.

---

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixtieth Annual Session, at Atlantic City, June, 1909.

Extracts of the tumor tissue in normal salt solution failed to hemolyze in a few cases of carcinoma, but the hemolysis was somewhat more constant with the extracts than with the patients' serums.

The hemolytic test was not affected in any way by vaccine treatment in the few cases studied, except possibly by tuberculin and Coley's fluid, as mentioned.

Table 4 shows the results of the hemolysis test in a variety of conditions, with the number of each:

TABLE 4.—HEMOLYSIS TEST IN VARIOUS CONDITIONS

Character of Cases.	No. Cases.	Positive Reaction.	Negative Reaction.
Carcinoma	42	36	6
Carcinoma removed	2	0	2
Sarcoma	9	9	0
Sarcoma removed	1	0	1
Endothelioma	2	2	0
Benign tumors	14	0	14
Tuberculosis*	43	..	36
Septic infections	35	3	32
Typhoid fever	22	7	15
Lobar pneumonia	6	3	3
Acute articular rheumatism	1	0	1
Tonsillitis	1	0	1
Elephantiasis of leg	1	0	1
Benign stricture of rectum	1	0	1
Duodenal ulcer	1	0	1
Cholecystitis	2	0	2
Cholelithiasis	3	0	3
Actinomycosis	3	0	3
Uremia	1	0	1
Diabetes mellitus	1	0	1
Grave anemia, secondary	1	0	1
Pernicious anemia	2	0	2
Exophthalmic goiter	1	0	1
Streptococcus vaccine	5	0	5
Staphylococcus vaccine	2	0	2
Mixed vaccine (strept. and staph.)	2	0	2
Pasteur vaccine	6	0	6
Tuberculin	1	0	1
Coley's fluid	4	4	0
X-ray	1	0	1
Normal	85	4	81

* Seven reversed reactions.

The normal cases showing hemolysis were all reexamined within a day or two, and no hemolysis occurred a second time in any of the four, as was true in subsequent examinations in these cases, indicating that the positive reaction was due either to some error in technic or to a temporary condition of the serums of those individuals. In many of the malignant cases two or more examinations were made, and in every case showing hemolysis the reaction was constant. The typhoid fever cases showing hemolysis were with one exception all in the fourth or fifth week of the disease, hemolysis in the one exception occurring during the second week.

The technic has not been materially modified from that used by Dr. Crile in his work. A few minor variations have facilitated the work somewhat. Placing the tubes upright for the clotting of the blood and obtaining clear serums has given better results in our hands than slanting the tubes. Corpuscles must be thoroughly washed, otherwise in hemolytic cases enough serum may be left to cause hemolysis of those corpuscles when added to normal serums, thus giving both a direct and reversed hemolysis and tending to confusion. The greatest care must be used in the preparation of all apparatus and solutions; otherwise the results can not be relied on.

CONCLUSIONS

1. The hemolysis reaction appears to be of decided value in the diagnosis of malignant neoplasms. Negative results do not rule out malignancy, but speak strongly against it.

2. The reversed hemolysis appears to offer valuable information with regard to the extent and activity of the tuberculous lesion.

3. Several examinations should be made in doubtful cases.

4. The reaction does not appear to occur in other conditions that would lessen its value in the diagnosis of malignancy.

ABSTRACT OF DISCUSSION

Dr. W. J. Butler, Chicago: I wish to refer to the great difference in the conclusions drawn by different experiments from practically the same results. With Dr. Mefford I examined a considerable number of cases to see what there was of value in the test. This work dates back to Maragliano, who, in 1892, called attention to the fact that the blood serum of patients suffering from various diseases frequently hemolyzed the corpuscles of normal individuals, and also those of other patients. We examined a number of cases, on which we have reported, made up of carcinoma, tuberculosis, typhoid fever, malaria, etc. Among the cancer cases, mostly of the stomach, uterus and breast, of which there were 22, 13 showed an hemolytic effect on the corpuscles that were used—a reaction in 59 per cent. Some of these hemolyzed the corpuscles of other cancer patients. In the tuberculosis cases, 3 of 8 cases showed the hemolytic reaction. One hemolyzed the corpuscles in another case of tuberculosis. I have never seen this reverse hemolysis, if I understand it correctly. As I understand it, it is the hemolytic effect of normal sera on the corpuscles of a tuberculous patient. Possibly the reason I have not seen it is because a comparatively small number of cases of tuberculosis were examined. All the patients were in the advanced stages of the disease. I can not attribute the failure to see it to defects in technic. On the contrary, I would regard failure to get it the best evidence of good technic. Of 5 typhoid cases, 2 gave a strong hemolytic reaction. There were 5 cases of pneumonia examined, 2 of which gave a strong isolytic reaction. In 2 cases of gastric ulcer, 1 of pernicious anemia, 1 of salpingitis, etc., isohemolysis occurred. I noticed that in nearly all instances in which isohemolysis was observed we got isoagglutination. There seems to be some relation between these phenomena. In only 3 among the cases that we examined did we get an isohemolytic action without isoagglutination. For these reasons, the results given by investigators differ widely. If you do not happen to have corpuscles of an individual that will be agglutinated by the sera you are testing, you will usually get a negative reaction. Individuals are divided into three groups, according to the agglutinating effect of their serums on the corpuscles of others. The serum of one belonging to Group 1 will agglutinate the corpuscles of Groups 2 and 3. Group 2 will agglutinate Group 3, but not Group 1. Group 3 will agglutinate Group 2 and may agglutinate corpuscles of Group 3. If you happen to have an individual of Group 3 whose corpuscles are agglutinated by Group 1 and Group 2, you will invariably get a positive hemolytic reaction with the serum of individuals suffering from various diseases, whether tuberculosis, malaria, pneumonia, cancer, etc. I regard the reaction as absolutely valueless from a diagnostic standpoint.

Dr. Frank Smithies, Ann Arbor, Mich.: My work has not been so extensive as that of Drs. Johnstone and Canning; I have not had an opportunity to take up so large a number of cases, nor to test some of the various phases of the technic. In all, I have examined 95 cases as to the presence of hemolysis in various diseases, especially cancer and tuberculosis. Of these, 14 cases were carcinoma, they proved to be so microscopically, by section; 58 per cent. gave a positive reaction; that is, there was hemolysis. Of these, the early cases were not uniformly positive. The late-stage cases were more nearly so, but there were some cases that did not give the reaction. Of 35 patients with diseases other than cancer or tuberculosis, 65 per cent. were negative. I had positive reactions in some of the anemias—2 cases of pernicious anemia, 1 case of Bright's disease, several cases of scarlet fever, and 2 cases of pleurisy; also in 2 patients who had been receiving the Pasteur treatment for hydrophobia. Nineteen patients with tuberculosis in all stages of the disease, were examined; and in only 2 did I succeed in getting the so-called reverse hemolysis. I might say, also, that in these 2 cases I was not quite sure that more experienced men than myself would have called it reverse hemolysis. These 2 cases were late-stage patients. In both there was abundant sputum and small cavities in the lungs. Of 28 clinically normal individuals, one presented characteristically typical hemolysis. The reason for this I can not explain. It may have been due to my inexperience with the reaction. In the paper on the action of crotalus venom, read in this Section, the statement was made that citrated corpuscles are less subject to hemolysis than those which are defibrinated by means of glass beads. I found this to be so, but my observation did not extend over many cases. Heated serum, in my experience, did not give the hemolysis. I believe that while a positive reaction is of great interest, I would not wish to take the serum test in itself as constituting final evidence. I think that there are many cases of carcinoma that do give this reaction, but these could quite as well be diagnosed by other clinical means. Possibly a longer series of cases will alter my opinion.

Dr. H. Noguchi, New York City: Has any study been made to determine if heterohemolysins are also increased in the serum of persons afflicted with malignant tumors? It would be of theoretical interest to investigate whether isohemolysin makes its appearance without being accompanied by an increase in the content of heterohemolysins. What effect will isohemolytic serum have on corpuscles of anthropoid apes?

Dr. H. G. Schleiter, Pittsburg, Pa.: In a series of examinations for hemolysis on 50 patients, 20 of which were subject to malignant disease, I obtained positive results in 15, or 75 per cent. Two of the negative cases were epitheliomata of superficial structures: the 3 remaining negative ones were well established cases of uterine carcinoma, confirmed at operation or by microscopic section. It has been my experience also that syphilitic cases tend to show rather uniformly a reversed hemolysis. This, together with the fact that various other pathologic conditions have, in the hands of different workers, exhibited a positive reaction, would seem to indicate that with the principles hitherto employed, there are so many confusing factors as to make necessary a considerable amount of further study before allowing this reaction anything like a specific diagnostic value—despite the fact that it would seem to have a confirmatory value in instances of malignant disease in the presence of positive clinical data.

Dr. O. P. Johnstone, Pittsburg, Pa.: Regarding the agglutination of the corpuscles and its relation to hemolysis, I have noticed agglutination in many of these cases, but have not observed any definite relationship between it and hemolysis. Many cases showed agglutination with no trace of hemolysis; others showed decided hemolysis with no agglutination. In defibrinating the blood I have ceased using the glass beads. Quite as good results are obtained by simply shaking the tube containing the blood, without the beads, and with less tendency to break the corpuscles or test tube. I have not had the opportunity to study the reaction in many cases of syphilis. I have had a few cases of tertiary syphilis in which the reaction was negative.

Regarding irregular hemolysis in cases not malignant and in normal individuals, I would say that from my experience it seems to be due more often if not always, to some error in technic. We have a good many points for errors to creep in, in performing the test, and must keep our eyes on all of them all the time—the test tubes, syringe, pipettes, salt solution, receptacles for the salt solution, the small tubes in which the test is finally set up, etc. These afford many chances for the introduction of some factor causing hemolysis, in some of the tubes and not others, or in all the tubes. Before we condemn hemolysis as being valueless because of irregular results we should check up carefully every point in technic. With caution and good technic, I feel that the test affords much valuable information in malignant conditions and tuberculosis. I would not advocate it, however, as a final and positive single test in either condition, but as one link in the chain of evidence. We must remember that a negative test does not mean the absence of carcinoma or malignancy, but rather that it speaks against such a condition, about 15 per cent. of such cases, however, failing to give the reaction. I have not studied many cases of epithelioma of the skin. I suspect that here the percentage of negative results of the test will be larger than in the malignant cases studied in this series.

Clinical Notes

CONGENITAL ABSENCE OF ONE KIDNEY

REPORT OF A CASE *

FRANCIS R. HAGNER, M.D.
Professor of Genitourinary Surgery in George Washington University.
WASHINGTON

Patient.—Mrs. H., 40 years of age, was referred to me by Dr. Gerry Morgan on Oct. 27, 1907. Family history was negative save that a sister died from pulmonary tuberculosis.

Previous History.—Patient suffered from diarrhea for thirty years; occasionally she had from eight to twelve evacuations daily. She was the mother of two children. The first labor was instrumental; the second was normal; there were no uremic symptoms either time. She had leucorrhea intermittently. In 1901 patient had excrutiating pain extending to the groin on the left side. This was followed by the passage of fifty-three stones via urethra. There was no blood passed at this time. For the succeeding two years she was practically free from symptoms; then she began to have attacks of pain similar to those experienced at the time the calculi were passed. No calculi were passed, however, nor were any passed since those referred to. In 1904 an ovary was removed; it was reported to me for an inflammatory condition. About March 4, 1907, the attacks of renal colic began to be more frequent; following each, large quantities of pus appeared in the urine, but no calculi were passed. In June, 1907, the patient experienced the most severe attack of pain, sharp, shooting and knife-like in character; this lasted for twenty-four hours, although the patient was given three grains of morphin. The attacks increased in frequency and severity. Just prior to her visit to me she suffered also from inability to void urine and on catheterization no urine was obtained. The first urine passed after these attacks referred to was very cloudy; urination occurred at intervals of fifteen to thirty minutes, and was accompanied by marked burning, but with no sudden stoppage of the stream. Every micturition was more or less painful and the patient was up from three to eight times nightly to urinate.

Examination.—The patient was a very stout woman weighing about 225 pounds; anemic and had every appearance of illness. She was so fleshy and so nervous that nothing could be learned by abdominal palpation. The examination of the urine showed a large amount of pus, a specific gravity of 1016, an acid reaction, a slight amount of albumin and 322 grains of urea in twenty-four hours. On October 29 the patient was examined under ether at Garfield Hospital. The left kidney was palpable, appearing enlarged; it was felt with difficulty as the patient was so very stout. The right kidney was not palpable. The patient was then cystoscoped. The trigone was inflamed but the rest of the bladder was practically normal. The left ureteral orifice was seen, appearing gaping and discharging turbid fluid. It was impossible to find the right ureteral orifice. The left ureter was then catheterized and urine identical with that obtained from the bladder collected. On microscopic and chemical examination there was practically no difference in these urines. A very careful search of the bladder was made but the right ureteral orifice could not be found. I had made such a careful search that I was sure only one ureter was present. An *x*-ray was negative for stone. I though at the time that she only had one kidney.

Under large doses of urotropin and water the condition improved; at least the patient thought that she was more comfortable. About the end of April she had repeated attacks of pain as described before and I felt that possibly opening and draining the pus from the kidney might prolong her life or at least make her more comfortable. Before operating I thought it best to make one more attempt to find the other ureter, so she was cystoscoped again on May 14. The left ureter was catheterized and the collected urine showed an analysis identical to that obtained on October 29. Very careful search revealed no other ureteral opening.

---

* Read before the American Association of Genitourinary Surgeons, May, 1909.

Operation.—The patient was operated on on May 19, 1908. The kidney was exposed, incised and about a pint of urine containing pus both free and inspissated escaped. No calculi were found. Drainage was maintained by fixing a tube in the pelvis of the kidney. The firm masses of purulent material passing down the ureter unquestionably had caused the severe attacks of renal colic.

Postoperative History.—After the operation practically all urine escaped into the dressings. Several bladder catheterizations obtained only a few drops of urine. The patient did very well for three days; she then began to vomit large amounts of fluid. A diagnosis of gastromesenteric ileus was made. Secretion of urine continued up to the time of patient's death, nine days after operation.

Autopsy.—On May 28: This revealed the presence of but one kidney. On the right side there was no artery or rudimentary vessel in the location of the renal artery. Careful search was made for an adrenal gland, but none could be found. The large pyonephrotic kidney was removed from the left side, together with the bladder. Careful examination of the bladder revealed but one ureteral opening, namely, the left.

Without cystoscopic examination and ureteral catheterization, I believe that this kidney would have been removed. Although the result to the patient could have been no worse than in this case, it is certainly more satisfactory to have made a correct diagnosis than to have removed a solitary kidney.

AN UNUSUAL STRANGULATED INGUINAL HERNIA

F. E. CLOUGH, M.D.

LEAD, S. DAK.

History.—J. T., aged 17, had had an undescended testicle in the lower end of the right inguinal canal since a baby without producing any symptoms. On July 13, while walking along a railroad track he stumbled and fell forward. In attempting to catch himself he felt something give way in the right inguinal region, but after resting for a few minutes, during which time he vomited once, he was able to walk to his home half a mile away. During the next two hours he vomited several times and had a great deal of pain in the region of the undescended testicle which had increased to twice its normal size. When seen three hours after the injury a diagnosis of strangulated hernia was made and an unsuccessful attempt made to reduce it under anesthesia. Immediate operation was then performed.

Operation.—On opening the canal, a hernial sac was located above and behind the tunica vaginalis, the neck of which sac was constricted. On opening the tunica vaginalis, a communication about one-fourth inch in diameter was found leading into the lower end of the hernial sac, so that the intestine which had passed into the tunica vaginalis was constricted both at that opening and at the neck of the true hernial sac. There was no other communication between the tunica vaginalis and the general peritoneal cavity. The hernial sac was separated from the tunica vaginalis and the neck ligated while the testicle, freed from adhesions and superfluous structures, was placed without any difficulty in the scrotum.

The patient made an uneventful recovery and is now doing moderately hard work six weeks after operation.

To Prevent Mosquitoes.—Dr. William Tell Kudlich has brought to the notice of the health board of Hoboken, N. J., says the *Scientific American*, a plan for exterminating the mosquito, which consists in planting mosquito-ridden tracts with arzolla. The plant is a native of Africa. It in a short time covers marshy land with a layer three inches thick, thus both suffocating mosquito larvæ and preventing the living insects from depositing their eggs in the water. The plant is said to have been used with some success in the German colonies of Africa.

AN UNUSUAL CASE OF INTESTINAL OBSTRUCTION

GEORGE W. ELY, M.D.

PITTSBURG, PA.

History.—H. J. F., male, aged 18, stenographer, was referred by Dr. G. A. Speer, Sharpsburg, Pa. There is nothing bearing on the disease in the history previous to April, 1907, when the patient had an attack of acute appendicitis, for which I operated and found a gangrenous appendix with a large abscess. The appendix was removed through a gridiron incision, a cigarette drain and some loose gauze being used for drainage and the wound partly closed by sutures. The drainage was left in for several days and the wound allowed to close by granulations; the process was completed in about six weeks without any unusual features. From that time until the present illness the patient enjoyed excellent health, with entire freedom from pain, bowels moving normally and regularly.

Present Illness.—On April 15, 1909, the patient was awakened at about 5 in the morning by intense abdominal pains, colicky in nature and generalized over the entire abdomen; he had a good stool which alleviated his suffering and he returned to bed and went to sleep; two hours later he was again awakened with similar pains, had another stool, and, feeling better, started for work, without any breakfast. Shortly, however, he had to return home and go to bed owing to the severe pains. At this time he began to vomit greenish-looking material, the vomiting recurring at intervals throughout the day, with no change in character. Dr. Speer was then called, ordered abstinence from food and drink, applied an ice-bag to the abdomen and gave an injection of morphin and atropin. The following day the patient's condition was practically unchanged, except that the vomiting had ceased; the bowels were moved by enema in a satisfactory manner.

Examination.—The next day the patient was referred to me and sent to the hospital, where his condition was found to be as follows: Temperature, 99.8; pulse, 84; respiration, 20; facies indicative of intense suffering, although slightly flushed, patient restless, and tossing in bed, thighs flexed and respiration labored. The abdomen was slightly distended and very rigid and tympanitic over its entirety, very tender to the touch, especially about the region of the navel. Nothing definite could be learned by palpation, while percussion elicited a slight tendency toward dulness in the right lower quadrant. The blood-count showed: reds 4,600,000, whites 11,000. Differential count: polynuclears 70 per cent., eosinophiles 2 per cent., large mononuclears 8 per cent., small mononuclears 14 per cent., and transitionals 6 per cent. Urine: a trace of albumin, a few casts, red and white cells.

Course of Disease.—The patient was placed in bed, put in the Fowler position and an ice-bag applied to the abdomen. No food or drink was allowed and an enema was administered, which was satisfactorily effective. During the following week the patient's condition continued essentially the same, the temperature ranging from 98 to 99, pulse from 72 to 80. The patient had a stool every day as a result of enemas administered. His condition was thought to be one of partial obstruction due to adhesions or constricting bands and operation was not deemed urgent. On April 25, 1909, he was feeling especially well until 4 in the afternoon, when he began to vomit fecal matter, became enormously distended, and suffered intense pain. His temperature dropped to 97.6 and the pulse went to over 100. No gas or feces could be obtained from the bowels by repeated enemas. The vomiting persisted.

Operation.—At 7 p. m. the abdomen was opened to the right of the median line, a little below the umbilicus, for here dulness could now be detected. As soon as the peritoneum was opened, liquid feces poured out with a gush; probably three pints or more were evacuated. It was then evident that there was an opening into the bowel, which was sought for. In doing this a loose piece of gangrenous intestine was encountered at the bottom of the cavity. It was about ten inches long and had the mesentery attached. After this was removed the proximal end of the divided intestine was brought to the surface and anchored there; a prolonged search was not made for the distal end of the intestine, as the patient's condition would not warrant overmuch trauma. The cavity left in the abdomen was large, and was completely walled off from the general peritoneal cavity by a firm wall of plastic material, incorporating in its sides some intestine and omentum. It was packed and drained and the skin wound partly closed.

Postoperative History.—The patient reacted very nicely from the shock of the operation, and for several days progressed favorably, but on the ninth day he had a severe hemorrhage from the depths of the wound, which was repeated at intervals, and he finally succumbed on the fourteenth day following operation from exhaustion. An examination of the abdomen after death showed a large cavity, effectively walled off from the general peritoneal cavity, into which opened both the proximal and distal ends of the intestine; and there was nothing present to give a clew as to the immediate cause of the obstruction, that is, as to whether it was due to bands, adhesions or a volvulus.

The interesting and unusual feature of this case is the fact that, although strangulation had taken place in the intestine so complete as to cause a slough *en masse*, yet there had been a stool every day since the beginning of the illness, the longest period between stools having been thirty-one hours.

It would be interesting to know just at what time the strangulation and separation took place; probably during the first part of the sickness. The proximal intestine apparently emptied its contents into the cavity, and when an enema would be given it would distend the distal portions, allowing the cavity thus to empty itself. The final, fatal obstruction was probably due to an obstruction in the distal end blocking the entire intestinal canal, producing a reverse peristalsis.

7105 Frankstown Avenue.

CYCLOPEAN MONSTERS

SOME GENERAL OBSERVATIONS, WITH REPORT OF A CASE

HARRY JACKSON, B.S., M.D.
Instructor in Pathology in Northwestern University Medical School
CHICAGO

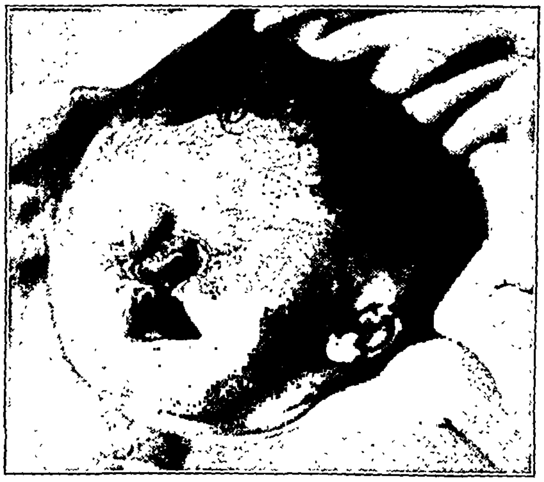
Many of us have seen cyclopia either among the lower animals, such as the pig, or in man, and not a few of us have wondered whether such monstrosities were a reversion to some early form in whom there was normally only one eye, or an anomaly due to maldevelopment of the normal two-eyed fetus. Physiologically, it has been determined that without binocular vision man can have little or no idea of depth or comparative distance. With but one eye constructed as ours is everything would appear flat. It would be interesting to examine the data at our command for any evidence of a uniocular man.

On prehistoric foundation, we have the report in the mythology of the ancient Greeks of a race of Cyclops with whom Odysseus tried conclusions. This race of giants very possibly was suggested to the imagination of the Greek by anomalies in Nature such as those we see to-day. The Greek likewise imagined many-headed monsters and beings half man and half beast.

There is no one-eyed stage in the embryologic development of man. Among the lower animals, however, this is not the case. Some of the peculiar embryologic forms called nauplius among the arthropoda have a single median eye-spot, and, singularly enough, an adult form of the same phylum, among the crustacea, retains the single median eye-spot. It is a fresh-water form, commonly found in our small lakes and ponds, and it is given the name "cyclops." Among the higher animals we find these median eye-spots associated with lateral ones in the spiders and scorpions. A median eye is not found normally among the vertebrata. In the frog there is a vestigial eye-spot on the dorsal surface of the head which is supposed to have some connection with the pineal body.

The cyclopean eye in the higher animals and man must be considered, then, as an anomaly, and many theories as to its origin have been presented. Folk-lore attributed it to bestial origin, just as the satyrs of Grecian mythology were considered half man and half beast. Maternal impressions, lack of oxygen, injury *in utero*, action of toxic substances and disease, all have been thought to play a part. Among more scientific students, two main theories have been presented. These may be briefly named the fusion and the germinal theories.

The fusion theory was the first to be advanced. As early as 1832, Geoffrey St. Hilaire[1] believed that in such monsters the more or less imperfectly developed visual organs approached the median line and eventually fused in proportion to the degree of atrophy of the olfactory organs. Later, Ahlfeld suggested that some cases were caused by intracranial pressure resulting in the rupture of the early cerebral vesicle at about the fourth week of embryonic life. He classified these monsters in successive grades, with characters ranging from a mere narrowing of the face with poor nasal development to a very imperfect single orbital cavity situated about the middle of the face, with or without rudiments of one or both eyes above a more or less rudimentary nose.



Cyclopean monster.

Those who believe in the germinal origin of cyclopia think that it is due to some defect in the germ cell occurring before the fifth week of embryonic life. Spemann and Stockard have produced cyclopean monsters at this period experimentally, both by mechanical and chemical means. Spemann[2] ligated eggs of urodele and triton in the two-celled stage and produced double-headed monsters with or without cyclopic defect. If, for example, he ligates at the two-celled stage so that the ligature coincides with the first plane of cleavage, a monster with two equal heads is produced. But if the ligature is placed obliquely to this cleavage plane, one of the component heads shows some degree of cyclopia. Stockard[3] treated artificially fertilized eggs with a solution containing a trace of magnesium chlorid and in this way he has produced cyclopean monsters repeatedly. Wilder agrees with Spemann and Stockard in their belief in the germinal theory, and in discussing the morphology of cosmobia[4] he outlines a theory in which the variations found in cyclopia are shown to be inherent in the germ and to develop along orderly lines. His classification of cosmobia, or orderly living beings, would include:

[1] St. Hilaire: Traité de tératologie. Paris 1832-1837.
[2] Spemann: Zool. Jahrb. Suppl., 1904, vii, 429.
[3] Stockard: Jour. Exper. Zool., 1907, iv, 2.

1. Cases in which the entire individual or the part involved is less than a normal individual.
2. Normal individuals.
3. Cases in which entire individual or part involved is more than one normal individual and less than two.
4. Separate twins, both normal.
5. (a) Separate twins, one of these a diplopage; (b) cases involving a single part in value between two and three components.[5]
6. Separate triplets, and so on.

Besides the question of the origin of cyclopia, the strange-looking proboscis seems always to demand special attention. This is present in most cyclopean monsters as a long, narrow, finger-like organ projecting from the middle of the forehead just above the median eye. It sometimes shows one or two orifices at its extremity. This is interpreted by most observers to be the frontonasal process which, according to Treves, gives origin to the external nose, the ethmoid, vomer, median portion of upper lip, and the intermaxillary process. In these monsters this frontonasal process is kept from growing down into its proper location by the mechanical difficulty interposed by the median eye and it, therefore, grows outward as a proboscis-like structure. We can readily see, in the light of this explanation, the cause of the cleft condition of the upper lip and palate and the absence of the nose as shown in the illustration of the specimen here reported.

REPORT OF CASE

History.—The patient, N. C., an Irish woman, aged 39, entered the Cook County Hospital, service of Dr. Roehler, Dec. 24, 1907. The house physicians were Drs. Nilsson, Smith and myself. The patient first menstruated at 15 and had had regular menstrual periods since that time. She had given birth to three normal children who were alive and well. She had had no miscarriages and no serious illnesses. She drank beer and whisky to excess. Examination showed a middle-aged woman in the second stage of labor. Her pains were severe, occurring every one or two minutes. She stated that she had been in labor five or six hours. The abdomen was greatly enlarged and a multiplicity of small parts was palpable. Two heart tones were distinguishable, one low down on the right side, frequency 135 beats per minute, the other to left of the umbilicus, 130 beats per minute. Vaginally, the cervix was found fully dilated and a head was felt with the small fontanelle to the right and anteriorly.

Operation.—As there was no advance of the head after two hours, the patient was anesthetized and low forceps applied. A normal female child weighing 4½ pounds was easily delivered. The second child now presented by the breech and was delivered manually to the head when difficulty was experienced. Forceps were applied to the after-coming head and it was delivered. This child did not breathe well on account of malformations of the head and face, and it died after two hours. The placenta, expressed one-half hour later, was found to be double with double membranes. It weighed 2½ pounds.

Description of the Second Child.—This child was a male, weighing 7½ pounds. It was moderately hydrocephalic and in the center of its forehead was seen a more or less fused double eye. The eyelids were scarcely developed, the lower one being incomplete owing to the cleft condition of the palate and upper lip. The pupil was incompletely double, the lateral diameter being three times as great as the vertical. A snout-like projection measuring 3.5 cm. in length and 1 cm. in width was seen springing from the middle of the forehead just above the median eye. In the center of the distal end was a small opening. A postmortem examination (Dr. E. R. Le Count) revealed nothing abnormal outside the head. The single orbital cavity, the absence of the olfactory and optic nerves and optic chiasmus make the brain specially interesting, and a more extended study of this part of the specimen will be published by one skilled in anatomic work.

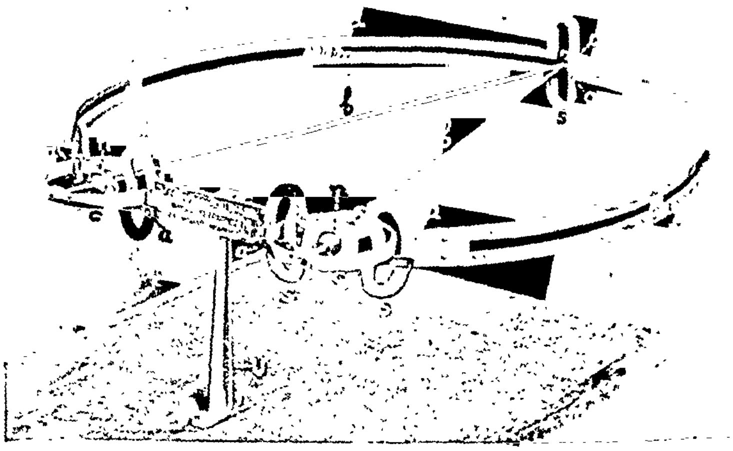
Thanks are due to Drs. Smith and Nilsson for permission to report the case.

365 East Fifty-first Street.

THE MUSCLE INDICATOR*

G. C. SAVAGE, M.D.
NASHVILLE, TENN.

In the Section on Ophthalmology at the 1908 session of the American Medical Association I presented a rough wire model of the instrument which now appears



The circle, *d—n—c*, is the primary isogonal circle, in the plane of which should always lie the two horizontal retinal meridians, *c* and *c*, and the two visual axes *b* and *b*. The center of rotation in each eye is represented by a ball-and-socket joint, *n*, through which the visual axis, *b*, passes on its way from the center of the macula out into space. The wire representing the visual axis of each eye consists in part of a tube by means of which it can be shortened or elongated. The two wires at their distal ends can be fastened by a hook-like arrangement so that they may not come apart while lying or moving in the horizontal slot, *d—c*. The vertical slot, *s*, in front is supplied with two clips, *a* and *a*, so that, when these are in place, one visual axis can not rise higher nor fall lower than its fellow, when the point of view is straight-forward. Turn the upper clip, *a*, to one side then one visual axis may rise above the other, or turning the lower clip, *a* to one side the one visual axis may fall below the other. In the first instance there would be shown hyperphoria or hypertropia, and in the last, cataphoria or catatropia. In both instances one visual axis has been allowed to leave the plane of the primary isogonal circle. When the four clips, at the slightly curved slots behind, are in place, the horizontal retinal meridians can not leave the plane of the primary isogonal circle. Turn the two outer clips to one side, leaving the two inner clips in place, the two horizontal retinal meridians can be tilted down-and-out, thus showing plus cyclophoria or plus cyclotropia. Leaving the outer clips in place and turning the inner clips to one side, the horizontal retinal meridians can be tilted down-and-in, thus showing minus cyclophoria or minus cyclotropia. In either instance the horizontal retinal meridians have been allowed to leave the plane of the primary isogonal circle.

If the second point of view lies on the primary isogonal circle, the visual axes and the horizontal retinal meridians shift in the plane of this circle while the plane itself remains stationary. If the second point of view be on some secondary isogonal circle, but directly above or below the first point of view, the primary circle is rotated to the position of the secondary circle, without any change of position of either the visual axes or the horizontal retinal meridians in its plane, the rotation being on the chord, *n-n*, connecting the centers of the two eyes, which is the only axis of rotation for the planes of all the isogonal circles.

---

[4] Wilder, H. H.: Am. Jour. Anat., December, 1908; criticized editorially, THE JOURNAL A. M. A., March 16, 1909, lii, 776.

[5] The case here reported is one of separate twins in which one of them showed cyclopic defect, the other being normal.

* Read in the Section on Ophthalmology of the American Medical Association, at Atlantic City, June, 1909.

in a perfected form (see illustration). I have named it the "muscle indicator" and claim for it that it will show every phase of any ocular muscle or combination of ocular muscles, normal or abnormal. It answers, I believe, every question that can be asked concerning the ocular muscles, and, moreover, concerning the brain centers that control the ocular muscles; in fact, it is, as it were, a talking machine, but it has to talk through me.

The device is of use not only in teaching, for it makes teaching of the ocular rotations perfectly easy, but also in the management of intelligent people suffering from muscle errors. There is no difficulty in showing the patient what the condition is and what ought to be done for its relief.

The circle is one of many million, all in the same plane. The primary circles, which this one circle represents, must all lie in the same plane, but only one can exist at a time. The circles formed in that plane are constructed through three points, two of them forever fixed and the other changeable. The two fixed points are the centers of rotation of the eyes, and the changeable point is the point of fixation. The next point of fixation may be inside this circle, or it may be beyond it an inch or any other distance to infinity. There are just as many circles possible as there are points in space directly ahead on the line of intersection of the vertical and the horizontal fixed planes of the head. Not only have we millions of possible primary circles, but millions of secondary circles also, all passing through the rotation centers of the two eyes and their planes intersecting in the line connecting these centers. Every object in space lies on one of these circles, and in studying the rotations of the eyes it is easy to see how they are effected and what the condition is. The law that controls the ocular muscles is simplicity itself. The superior and inferior recti must keep the visual axes in the plane of the primary circle. The lateral muscles must regulate those in this plane. The obliques must forever hold, except under abnormal conditions, the horizontal retinal meridians in the plane of this circle, as well. If one visual axis rises above that plane (hyperphoria) it is shown on the instrument. If the retinal meridian tilts it is shown. There is not a possible state of the ocular muscles but what this instrument can show, and there is not a nerve center that controls the ocular muscles that can not be demonstrated by it.

THUMB-LIKE EXCRESCENCE ON THE TONSIL

EMIL AMBERG, M.D.
DETROIT, MICH.

Mrs. C. S. H., aged 42, consulted me in June, 1909. The right tonsil showed a thumb-like excrescence at the lower posterior border. Before the tonsil was removed this excrescence annoyed the patient considerably. The patient coughed in the morning and as soon "as the air changed." On June 9 I removed both tonsils, in Harper Hospital, under local anesthesia, anesthetizing the surface, and also injecting in the usual manner into the surrounding tissues a 0.5 per cent. alypin solution in suprarenalin solution, about 1 to 10,000, which were sterilized by boiling. The tonsils were enucleated. The left tonsil does not show any excrescence. The patient seen in my office in September looks much better. She reports that the annoying local symptoms have disappeared and that her general condition is much better.

INTRACANICULAR FIBROMA OF THE FEMALE BREAST UNDERGOING SARCOMATOUS CHANGE

EMANUEL FRIEND, M.D.
Instructor in Surgery in Rush Medical College (in affiliation with the University of Chicago)
CHICAGO

Fibromata of the female breast are sometimes pure and sometimes in combination with adenomata, sarcomata, myomata and cysts in the form of fibrosarcomata, fibromyomata and fibrocystomata. Fibromata develop mainly from proliferation of the connective tissue surrounding the acini and the small excretory ducts (pericanalicular fibroma). They are most frequent in young persons from seventeen to thirty years of age and are very rare beyond the fortieth year.

Pure fibromata usually form in even, solid nodules of about the size of a walnut or a hen's egg, which, in contradistinction to carcinomata, are freely movable within the breast. In rare cases, especially when combined with cystoma, fibromata attain considerable size. Schimmelbusch classifies cystosarcoma, phylloides (J. Muller), myxoma intracanalicular (Virchow) and serocystic sarcoma (Brodie), all of which tumors may attain an enormous size among the benign fibroadenomata, and thinks they should be distinguished from the true cystic sarcomata.

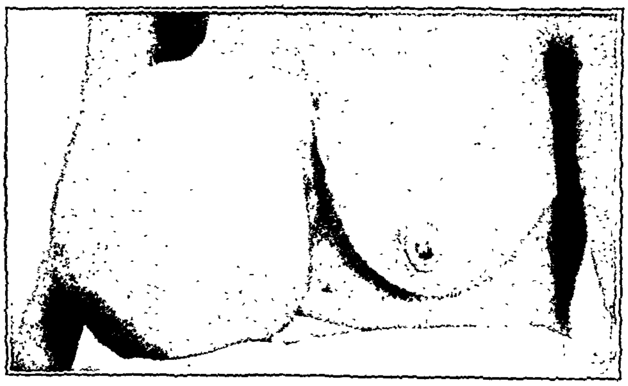

Fig. 1.—Photograph of patient showing tumor and its effect on the skin and fascia.

The tumor to which I wish to call attention I should properly include in the second and third variety of true fibromata of the breast, the first being a tuberous, localized form of connective tissue tumor about the size of a walnut, typically encapsulated, its primary origin being in the interacinous connective tissue.

The diffuse form, with general enlargement of the breast, simulates a mastitis in which the glands or ducts are separated from each other by excessive connective tissue, which predisposes to cyst formation. This cyst formation may be only the dilated gland itself or the duct or a combination of the two caused by an obstruction to its outflow. The intracanicular form grows to a considerable size and the proliferated connective tissue pushes its way into the acini of the gland, carrying the basement with its overlying cells before it.

Patient.—Mrs. B. G., aged 54, housewife, was admitted to the hospital June 17, 1908.

History.—Father died thirty years ago from an unknown cause. Ten years ago mother died, cause unknown. Has two sisters and one brother all living and well. Patient has had four children, all boys. Two dead, one one hour after birth; the other about three years after. The other two are living. The last baby was a forceps delivery, other three normal

Menopause at 52 years; previous to this time menstruation was perfectly normal in every respect. Three or four years ago she had her first attack of pleurisy affecting at that time only the right side at base of lung. Two or three times she has had repeated attacks on the right side. Last spring she had pleurisy on the left side for the first time. From childhood she has suffered from migraine.

Present Illness.—The patient stated that about ten years ago she noted a hard nodular lump about the size of a hen's egg located in the upper and inner quadrant of the right breast. It was absolutely painless and she paid very little attention to its growth. About fifteen months ago she became bed-ridden with a severe bronchitis. After she had been ill for about a week she noticed for the first time that her entire right breast was getting larger. She was unable to give any definite information as to whether or not the enlargement was due to an increased growth of the lump noted ten years ago. She thinks, however, that the enlargement was general, progressive and independent of the small nodular growth. The right breast became larger and larger until it has reached the present size. It had always been painless, and it had never given her any trouble other than its weight. The patient stated that she believed it became somewhat smaller about four weeks after it began to increase in size, but soon after she noticed that it began to again increase in size. She had lost very little weight in the last ten years.

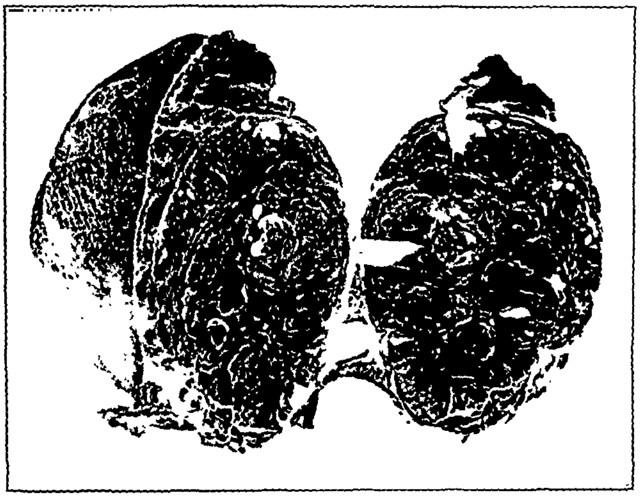

Fig. 2.—Cross-section of the gross specimen showing dense columns of connective tissue with cysts interspaced and filled with colloid material.

Examination.—General appearance was that of a frail, poorly nourished woman, past middle life, complexion dark, hair slightly gray. The left breast was small and atrophied; negative as to tumor infiltration. The right breast was symmetrically enlarged to about the size of her head; the nipple was not retracted; on the surface could be seen enlarged veins; no pulsation. The skin over the breast was slightly red in color. There was no lymphatic enlargement.

Operation.—Anesthesia, gas and ether, Dr. Morrill. On June 20, 1908, an amputation of right mamma was done under gas and ether anesthesia. The typical Halstead incision was made, extending from the axilla around the breast; skin was then undermined and breast shelled out. The axilla was then explored; no glands palpable. Tumor was cystic in places. Skin was closed with a running silk suture; rubber drainage tube inserted in axilla and at lower angle of incision. Wound was sealed with colloidion and dry dressing applied; arm bandaged to chest in flexion. Patient returned from operating room in good condition.

Histologic Report.—I am indebted to Dr. Herzog for the following report: The tumor after removal was not dissected, but was left undisturbed and fixed in Kaiserling's fluid No. 1. After having been therein for several days it was divided by a median section along the long axis and then placed again in the fixing fluid for several more days. After the return of the natural color, in 80 per cent. alcohol, it can be seen in the cut surface that the main mass of the tumor is made up of solid tissue which in arrangement and appearance looks very much like a fibromyoma or a fibrosarcoma. The solid parts, however, contain a number of spherical or oval spaces, which are filled with a material which was more or less fluid before hardening, but which is now semi-solid or gelatinous.

Microscopic examination of sections shows that the most characteristic parts of the tumor contain glandular spaces lined by columnar or cuboidal epithelium. These gland spaces look exactly like those seen in the mammary tumors usually called fibroadenoma or *fibroma peri- et intra-canaliculare*. Some of the spaces formed by the epithelial cells have become very large and cystic, of a size rarely or never seen in an ordinary fibroadenoma. These cysts contain a hyaline material which does not stain as deeply as true colloid does, but moderately deeply like ordinary hyaline. Where this material is present the cystic spaces are lined by very flat epithelia, their diminished size being evidently due to pressure. The connective tissue surrounding the gland spaces generally forms powerful tracts. In fact, the great mass of the tumor is composed of connective tissue formed mostly of spindle cells and fibers. In some parts, the spindle cells have evidently proliferated rapidly and have formed a tissue decidedly embryonic in character.

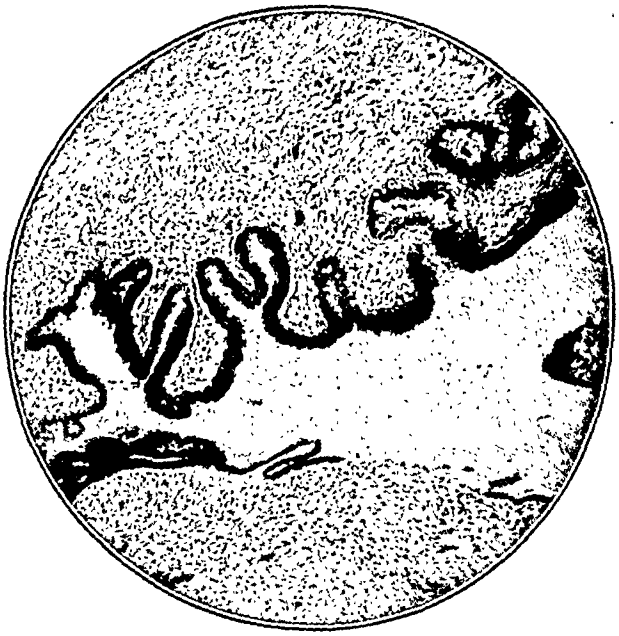

Fig. 3.—Microscopic picture (1/7 objective) of connective tissue bundles (showing the overlying acini) undergoing rapid cell multiplication.

On the whole, the tumor creates the impression that we are dealing with an original fibroadenoma which has undergone a sarcomatous metamorphosis or metaplasia. The marked destructive tendencies of a pronouncedly malignant tumor, however, are missing.

Gross has established the following facts in regard to the permanent cure of sarcoma based on 92 cases: Twelve patients remained well 4 years or longer, 42 had local recurrence, most of them (57.7 per cent.) within 6 months, on the average, at the end of 10 months and a half in some cases, after from one to four years. The tumors in young persons, and those in whom the gland is active, showed a pronounced tendency to recur and less to form metastases, while the reverse was true in sarcoma of a mamma that was undergoing involution. As compared with carcinoma of the mamma the sarcoma inclines more to metastases and less to local recurrence. The lymphatic glands are affected much more frequently (67.4 per cent.) in carcinomata than in sarcoma (0.64 per cent.). According to Horner's statistics, 76.92 per cent. of the patients operated on remained free from recurrence longer than 2 years, 61.54 per cent. remained cured. Paulsen states that 75 per cent. of his patients, and those collected, remained well after 5 years and 25 per cent. died of metastases.

AN IMPROVED EYE-BANDAGE

C. W. TALBOT, M.D.
SPOKANE, WASH.

There are many good eye-shields on the market today, yet the one I show in the accompanying photographs I have found superior to anything I have seen.

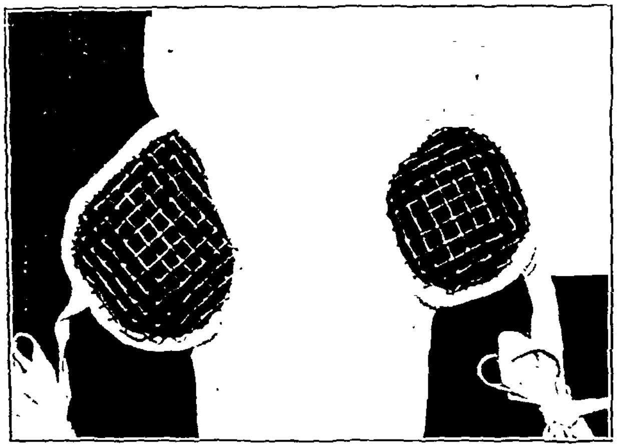

Fig. 1.—Improved eye-shield, universal form.

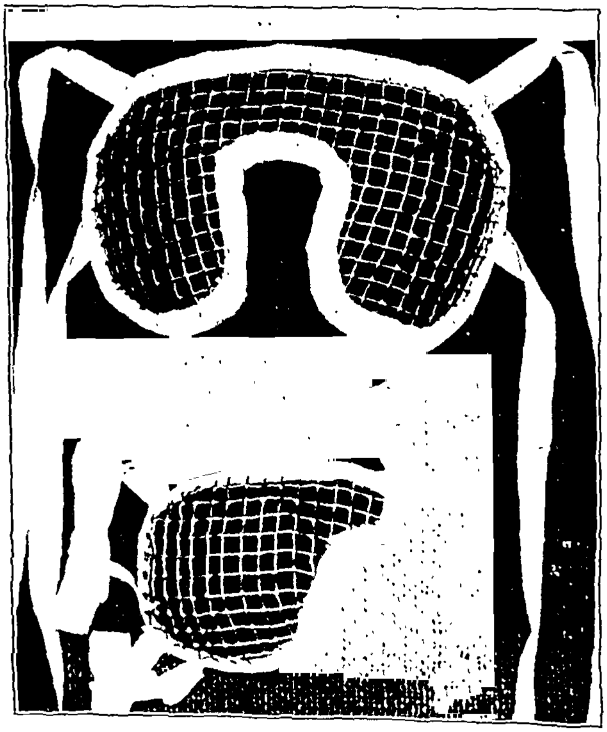

Fig. 2.—Improved eye-shields, both eyes and one for the right eye.

This eye-shield is made of quarter-inch galvanized wire netting cut to shape and the raw edges covered with cotton, after which it is bound with ordinary cotton or linen tape and the ties sewed on.

The advantages are that it is easily put on and off by the patient; that the tension is readily changed, permitting compression as well as immobilization of the lids, and that fresh gauze can be put in as often as it becomes soiled, which is quite an item when the patient is not seen daily; that it can be readily cleaned by the patient with a little soap and a hand-brush and is easily sterilized, and that it does away with the hot bandages around the head and is, therefore, much cooler, more sanitary and altogether more pleasing to the patient than any form I have ever used. I have been using this form for over three years now and find it very satisfactory, indeed.

The universal form (Fig. 1) is suitable for either eye, but for purposes of compression the rights and lefts are more desirable.

Figure 2 shows a double shield above and below it one for the right eye.

Figure 3 shows the right shield (without gauze) in position, the lower tie passing under the right ear and the upper tie above, one passing through the loop and being tied on the left side of the head; the shield can readily be loosened or tightened to suit the comfort of the patient.

The shield can be bent in any shape so as to fit down snugly over the nose and cheek; it is deep enough to permit the use of a large pad of cotton gauze.

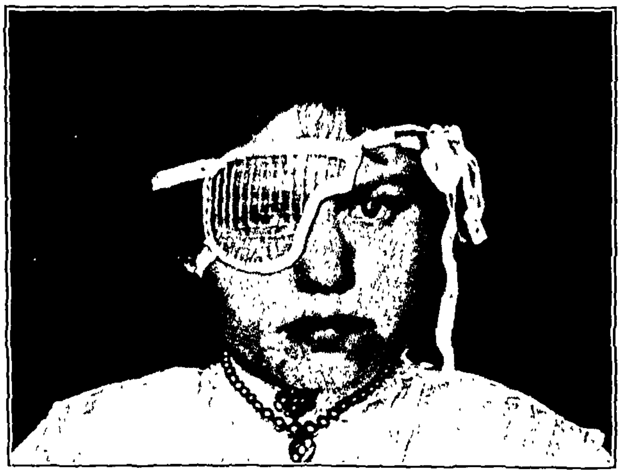

Fig. 3.—Patient wearing eye-shield.

As a postoperative bandage this shield is invaluable; in purulent conjunctivitis it can be used without gauze and yet protect the eye from being touched, thereby preventing the infection from being carried to the other eye —a very important point to consider in children.

Since the cost is trivial a shield is used only once.

A METHOD FOR COUNTING BACTERIA IN THE BLOOD

FRANCIS T. B. FEST, M.D.
WITH THE COLLABORATION OF
H. J. HOAG, M.D.
LAS VEGAS, N. M.

The pipette, in use for the leucocyte count with the Thoma-Zeiss hematocytometer or its modifications, is filled in the usual manner, blood being drawn to the 0.5 mark and the melangeur filled to 11. For the dilution we use a solution of 2 per cent. sodium citrate and 1 per cent. of sodium chlorid in water. Of this diluted blood, 1 milligram is measured with an accurate hematocrit scale or a specially marked, fine pipette. This milligram is distributed over a warmed slide in fine drops deposited in a row. About eight droplets usually will use up this quantity of dilution.

It is of the greatest importance to make the droplets as small as possible. The drop-films are allowed to dry well. They are next fixed with a mixture of 3 per cent. acetic acid in alcohol. No heat must be applied. When fixed thoroughly the films are stained intensively with borax-blue. Several slides are prepared in the same manner.

The number of bacteria in each film is counted separately and all added together. This counting will be easy if the films are small. The sum total of the bacteria is divided by the number of slides used and multiplied by twenty. The result is the number of microorganisms in 1 milligram of the blood.

While borax-blue is not a differential stain, differentiation must be done in each case before the count is undertaken either by suitable special stains or cultures. It is best for the differentiation of tubercle bacilli or pneumococci to apply the Gram- or the Spengler-stains. In order to obtain a large quantity of the blood-dilution, the diluting can be done in a properly graduated tuberculin syringe. This enables the beginner to prepare a large number of slides and to select those with the finest drop-films.

It stands to reason that it is well to prepare and to count a fairly large number of slides, because the average obtained thereby will give a more exact result than if only few slides are counted.

National Pythian Sanatorium.

Therapeutics

PSYCHOTHERAPY

Discussion of this broad subject is not attempted here, but it is intended simply to point out the necessity for a better general understanding of the subject by physicians. No one to-day questions, if there ever was any question, the power of the mind over the body, and its interpretation of functional disturbances, abnormal conditions [illegible] processes. It is true that the so-called [illegible], or condition, is on the increase, this of necessity from the kind of lives that are led in civilized regions. It is also a fact that with a better understanding of disease and pathologic processes unavoidably mental conditions occur that so misinterpret functional disturbances that the physician is fooled, by the patient's description of symptoms, into the belief that pathologic processes are actually present. Such patients naturally are not benefited by specific treatments directed toward the pathologic process supposed to be present, and consequently pass from physician to physician, and are finally cured by some one of the many unscientific methods of appealing to the mind.

It should be understood in interpreting apparently wonderful cures by mental impression that, in the first place, such cures have always occurred since there has been a history of man. Also, there is no disease or condition, however conclusive the diagnosis and hopeless the prognosis may be, but that occasionally has shown miraculous recovery. Therefore, there is no unscientific treatment of patients but that has had its ordinary cures and its apparently wonderful cures, but only the celestial recorders know the hundreds and thousands of failures and the dire disaster that has been caused by such unscientific methods.

All successful physicians appeal more or less to the minds of their patients in establishing a cure, recovery or improvement of any disease or abnormal condition that may be present. Most physicians use tangible means to aid in securing mental improvement and causing mental strength in patients who need mostly mental treatment. Such methods, whether by placebos, electricity, baths, physical therapies of varying kinds, climate, travel, change in diet, or periods of rest, have all done good work for years.

It has been almost an insult to a patient to tell him or her, and generally her, that there was nothing the matter with her except as she thought it. This was not only so considered by the patient, as she "guessed she knew how she felt," but was also considered an insult by the family, and another physician would be obtained who did not so bluntly tell the truth. The development of an age in which the patient and her family must know all of the scientific and pathologic truths in regard to her condition, and the various mind curists having lauded their methods of treatment at this same time (self-drugging and "patent medicine" taking, and the strong harmful ingredients that were contained in "patent medicines," all being described to the public as vicious) have made the patient and the family more willing to be told that nothing is the matter with her except mental disquietude, or psychologic misinterpretation. Therefore, the opportunity for the growth of mental training, which has had its basis on splendid study and research by the scientists in this line, has arrived, and the necessity for such scientific treatment of neurotic, nervous, neurasthenic and hysterical patients is unquestionable.

Unfortunately, until the lay education has gone a little farther, patients and their families are more willing to be told that they need no treatment, other than mental, by unscientific, uneducated and mercenary practitioners than by the honest physician. They are also more willing to try a drugless treatment of disease prescribed by a quack than they are when such treatment is prescribed by a physician. This, however, is only a stage in educating the public to recognize the ability of the trained physician to treat, improve and to cure generally his patients, mentally and physically, more rapidly and more surely than any non-religious, [illegible] religious, half-medical, dietary, non-dietary, or sheer mercenary quack on earth.

There is danger in all mental treatments, whether exercised by those of particular kinds of faith, practicing under particular kinds of title, or whether by so-called church movements in which men educated in lines other than medicine take up the treatment of medical conditions. It is perfectly absurd to consider that disturbance of a kidney is medical and disturbance of a mind religious. There is no question that religious or mental ecstacy or self-hypnosis developed in any way by church movements, or other, may prevent a patient (or even cure him) noticing disturbances that are functional, pain that is neuralgic or even symptoms of organic disease, but as the religious healer or curer, or mental trainer has not studied pathology, and the patient has not studied pathology, and neither of them can differentiate the indications of a serious, or even contagious, disease from mental crookedness causing telegraphic messages or even wireless messages to different parts of the body, such methods of treatment are dangerous to individuals and to a community.

The clergyman, who visits a home where there is sickness, in conjunction with the physician, bringing hope, mental help, good will and cheer to the patient and family, makes the treatment of the illness ideal. A physician who does not treat, aid or help the mental part of his patient's entity should not practice medicine. On the other hand, the clergyman who attempts to treat patients who claim to be ill, without an examination and diagnosis having been made by a physician, is criminally careless, and should no more be allowed to practice in this manner than is a physician allowed to write a prescription without having successfully passed a state examination. Either is dangerous to the community.

It can not be denied that some men, and they may be theologians, have more hypnotic power than many medical men. They are accustomed to control mentally, as well as more or less successfully religiously, their parishioners. They talk forcefully and lead well, and ideally they are in many instances admirably fitted to teach mental strength, but they should study pathology and thoroughly recognize the limitations of their ability to cure, should always have a patient examined by a physician before they attempt to treat him or her mentally, and should never so exalt or stimulate individuals of a family to the point of physical and medical neglect of other members of that family who may need the care of a physician or surgeon.

It is also perfectly true that while some medical men have force sufficient to control hypnotically and to give mental strength to the patients whom they are treating, others have not such forcefulness, and they, in individual instances, should call to their aid a man who is able to train the patient's mind.

The main point that it is desired to enforce is that physicians as a whole are entirely unqualified scientifically to treat a patient psychically, i. e., psychotherapeutically. Men who have devoted years to scientific investigations of mental training and to the study of the human mind and to the management of patients who are ill mentally only (and by this is not meant insanity) should be consulted when a patient needs psychotherapeutic treatment only. Physicians should prepare themselves by a careful study of the science of psychotherapeutics, beginning with its fundamentals and then work gradually up to the actual practice before they are ready to treat psychologically to the best advantage of the patients. The best medical schools, hospitals and dispensaries are beginning to instruct the students and internes on this subject. Unfortunately, the clinical material that comes to public institutions is not mentally similar to patients whom one sees in private practice.

Patients who are neurasthenic are not necessarily best treated psychotherapeutically. While the majority of them do well so treated, and all may need some of such treatment, the diagnosis of neurasthenia by no means necessarily means that there is nothing the matter with the patient but mental disturbance. Loss of weight is always an indication that the patient is below par, and it certainly should be the physical and mental object of the physician to build this patient up to normal. Mental fatigue certainly predisposes to physical ailments and an exaggerated interpretation of physical ailments. Consequently, patients in whom such mental fatigue is diagnosed should be mentally rested, and not mentally stimulated to believe that nothing ails them but as they think it.

The interpretation of the self-same injury to sensory nerves varies greatly in different individuals. Consequently, to decide that a patient does not suffer the amount of pain he claims he does, because in the physician's or in the layman's experience such injury causes only half the amount of pain that is claimed, is unfair to the patient. It may be true that the pain is grossly exaggerated, but it should be remembered that neither the physician nor the bystanders really know, and the patient should be given the benefit of the doubt. It is, however, perfectly true that a given individual may apparently suffer twice the pain at one time which he has suffered at another time from the same condition or injury. This may be due to mental tire, to mental excitation, or to loss of mental control. If acute pain is actually suffered, mental treatments, even to the attempt to produce hypnosis, are of but little avail. The mental stimulation, education and treatment should be given during the interims from actual pain.

The Weir Mitchell rest cure of neurasthenic and hysterical patients is of vast benefit in many instances, of some benefit in most instances, but occasionally signally fails. It requires the most careful discernment and discrimination to decide whether, in the individual instance, the patient should receive the "rest cure." At times patients who are introspective, who are not mentally weary, and whose nutrition is pretty good, are positively injured by such treatment. Such patients need mental training given by some one who is educated in that line of treatment. Other patients, with symptoms of physical and mental debility, and who are surrounded with worries and frets, recover only by prolonged rest, and best in a sanatorium prepared to treat such patients. Such treatment, however, is the most successful when the attending physician and the physician in charge recognize the power of physical treatments, mental stimuli and mental training more than the mere rest and medicine.

If the physician decides that the patient has no organic or serious functional disturbance and that the symptoms are produced by mental mistakes, and he decides that he has the mental forcefulness, power, understanding, and training sufficient to treat this particular patient, it is wise first to explain to the patient the nature of the condition and the reasons that certain symptoms occur, their lack of seriousness, and the absence of any pathologic excuse. Individual disagreeable symptoms should be modified by any physical or medicinal treatment that seems necessary, such medicinal treatment being stopped just as soon as possible, and the patient's mind trained to overcome the disturbing symptoms that called at first for treatment. The mind of the patient should be trained to think in lines that are not personal, and to take up lines of thought or study that will keep healthy parts of the brain so interested or satisfied that the parts that have to do only with physical sensations are less important, overlooked, or controlled. It is well also to arrange the patient's life so that the day will be busy. All this part of the treatment must be individualized to change the thoughts, habits, and interests of the individual patient. It is perfectly true that placebos and various physical treatments, such as varying kinds of electricity, must be used more by the physician than when the same patients are treated by quack methods, because the latter methods are surrounded by mystery and the mind of the patient receives the stimulus of hope and recovery because the methods are so strange and mysterious. This is only going back in mental beliefs to the dark ages, and man has not even now overcome his association of disease and cure with the Devil and magic.

SATURDAY, OCTOBER 30, 1909

THE CONVEYANCE OF BACTERIA BY SEWER-AIR

For years after Murchison announced, in 1858, that typhoid fever was produced by emanations from decaying organic material, sewer-gas was held responsible for many infectious diseases. The cause of the large mortality from "zymotic" disease in cities by many was traced largely to sewer-gas poison. While other causes were not wholly excluded, to bad plumbing was attributed the principal part in causing "pythogenic" pneumonia, peritonitis, inflammatory rheumatism, typhoid and malarial fevers, croup, diphtheria and many kindred diseases.

According to the germ theory of disease, sewer-air can cause infectious diseases directly only by the conveyance of germs, and the question whether it actually does convey germs has received much attention. Bacteriologic examinations of the air in sewers showed it to contain only a small number of bacteria, and these were common to street air rather than to sewage. These results, coupled with the absence of any reliable indications from the study of epidemics in favor of transmission of infectious agents by sewer-air, led many sanitarians to conclude that the danger of such transmission was small enough to be disregarded. But the recent experiments of Major Horrocks of the English army gave results which served to revive the suspicion that sewer emanations may be the cause of mysterious outbreaks of disease. He introduced known bacteria, such as the *Bacillus prodigiosus* and the *Bacillus coli*, into drainage systems, in the upper parts of which he exposed dishes of culture media. He thus recovered his test bacteria in various parts of the systems, in one case even at the height of fifty feet above the traps, showing that specific bacteria present in traps and drains can get into the air above by splashing and bursting of bubbles and, in some experiments, possibly even from the surface of liquids apparently in quiet motion.

In view of the apparent difference between the results of Horrocks[1] and those of previous investigators (Miquel, Haldane, Laws and Andrewes, and others), Winslow,[2] at the instance of the Sanitary Committee of the National Association of Master Plumbers, investigated the question of bacteria in sewer-air. Winslow's early experiments gave results like those of Horrocks to the effect that bacteria may pass from sewage into the air above and be carried for considerable distances. The proportion of positive results, however, was small and it was determined to use quantitative methods. The bacteria that happen to fall on plates exposed, as in the method used by Horrocks and later by Andrewes, to the air in sewers are not related to any particular volume of air. Winslow used a new method, by which the bacteria in a measured volume of air drawn into large culture-bottles are allowed to settle on media in the bottom of the bottles. Foaming bacterial emulsions were poured rapidly into water-closets and samples of air collected at the crown of the upper trap. Here everything now was favorable for the discharge of bacteria into the air, but, of forty-four liters of air examined, forty-three did not contain any bacteria. One liter showed a group of eleven colonies, derived perhaps from a single infected droplet. The actual conditions as they exist in different plumbing systems were next studied. The pipes were tapped at various places, and in each case ten one-liter samples of air were drawn into culture bottles. In one hundred and ninety-seven satisfactory tests of this kind, forty-eight samples gave bacteria capable of development at 37 degrees C.; only four contained sewage bacteria, and in collecting these samples of air mechanical spraying of sewage took place at the point of collection. The results of Winslow's experiments consequently support Horrocks in so far as they show that bacteria may be ejected from liquids in sewers into the air above, but at the same time they show that the general air of house drainage systems is singularly free from bacterial life.

The sum and substance of the matter seems to be that bacteria may pass from sewage into sewer-air, but only in such small numbers as scarcely to affect its general composition. There is, therefore, little reason to believe that sewer-air needs to be feared as a means of conveying infectious diseases.

THE SPAN OF HUMAN LIFE

It is often asked if men do not live longer now than formerly—if the length of human life is not actually increased? It is evident that two distinct problems may be hidden in this question as it is ordinarily put. The first relates to what may be called the natural term of existence. The duration of a normal life not cut off by accident or infectious disease was placed by the Psalmist at about threescore years and ten; seventy or eighty years is, indeed, to-day commonly reckoned as the normal life.

There seems to be no reason for supposing that within historical times man's natural term of life has materially varied. Like that of the dog or the horse, it is determined by unknown biologic causes. While some statements in old documents might be taken to indicate that in antiquity men lived hundreds and even thousands of years, such assertions appear to be based on wrong interpretations of time-units or on pure fable. It has been alleged that a larger proportion of persons lived to reach the age of 100 years at certain earlier periods than at the present day, but this belief rests on an equally insecure footing. As is well known, the investigation of alleged instances of centenarianism has shown that many of these cases will not stand examination and that some even are examples of deliberate fraud supported by such devices as the substitution of birth certificates.

---

[1] Recently the results of Horrocks were confirmed by Andrewes, who used the same methods.

[2] Am. Jour. Pub. Hyg., 1909, xix, 640.

Unimpeachable records of the proportion of long-lived individuals to the total number of persons in the community do not exist for any considerable period. So far as the meager modern statistics go, they indicate that the proportion of 5-year-old children who live long enough to reach their eightieth year is really not greater now than it was at the beginning of the nineteenth century.

Quite different is the answer to the second question implied in the ordinary inquiry concerning an increase in longevity. A new-born child has certainly a better chance of living a long life now than he had even a few years ago. This may be shown in various ways. The remarkable decrease in mortality during the first five years of life is especially well known. In practically all civilized countries a decline in the death rate among young children has been observed and is apparently still taking place.

In Germany, for an example, 290 out of every 1,000 living new-born children died during the first five years of life in 1890, since which year the number of deaths in the same age-group has sunk to 230. It is a matter of common knowledge also that the average mean duration of life has appreciably risen in the last half century and in some countries has increased at a rate of about two years in each decade. In Norway and Sweden, where statistics show the infant mortality to be very low, the average duration of life is now as high as 52.25 years!

A particularly important measurement of improvement in the conditions of life consists in the determination of the lengthening of the working period, for example the years between 15 and 60. There seems to be taking place a steady increase in the number of persons able to live through this important span. In Sweden and Norway the average number of years lived by each 15-year-old child was 35½ (out of a possible 45 on this method of reckoning) at the beginning of the nineteenth century, while it was 38½ at the close. In Germany an almost equally great improvement is said to have occurred within two decades. It is not, therefore, alone in the earlier years of life that a genuine reduction in mortality has taken place. The average duration of human life is greater, even though the natural term of existence has not been altered. In this sense human life may be said to have been materially prolonged within historic times.

PHARMACOPEIA REVISION

We publish this week under "Correspondence" a letter calling attention to the reports on the Pharmacopeia of three committees of sections of the Association.[1] As our correspondent remarks, these reports furnish much food for thought to physicians interested in the development of sane drug therapeutics; and what physician is not interested in this subject? The recommendations contained in these reports came from men actively engaged in the practice of medicine—those, in fact, who are bearing the brunt of the battle against disease. Their opinions are worthy of careful consideration even by those who are not especially interested in the purpose for which the reports were primarily prepared. The fact that so many of the members of the Section on Ophthalmology, for example, state that they have found certain drugs of very distinct value and others of little or no use is an item which should prove of great interest to their colleagues. The primary object of these section committees is to collect material which will indicate to the Committee on Revision the desire of the medical profession concerning the scope of the Pharmacopeia.

The reports have a special significance, as they show a tendency on the part of physicians to assume again their share in the important work of revising the Pharmacopeia. That physicians have in recent years greatly neglected this is a matter of common knowledge; that the result has been unfortunate is also well known. The chemical and pharmaceutical part of the work of revision has been exceptionally well done, but the medical part (which, in the words of the founders of the Pharmacopeia, should be "to point out those articles of medicine which they (the physicians) shall ordinarily employ") has been less successful; this is sufficiently evidenced by the protests which have been made against the retaining of many of the preparations which were admitted less than five years ago.

The methods pursued concerning admissions by the last Committee on Revision are not such as to appeal to the medical profession; the committee was all too willing to yield to what was represented to be the wishes of physicians and evidently took little trouble to inquire how extensive or how well founded these wishes were. In fact, a member of the Committee on Revision expressed the view that if a large number of physicians habitually used brick-dust, believing it to be a remedial agent, then brick-dust should go into the Pharmacopeia. With the Committee on Revision holding this view (just how the representatives of the medical profession reached such a view of their functions we do not understand) it is not surprising that a number of preparations of ephemeral interest, or fads, as a member of the Committee on Revision termed them, were admitted. This passive attitude reminds one of the frequently heard argument that any demand, however pernicious it may be or however artificially it may have been created, should be supplied. Such reports as these of the section committees should stimulate discussion as to the real value of some of the new drugs and aid materially in making the Pharmacopeia more representative of the best (not the worst) in the practice of medicine.

THE SCIENTIFIC MESSAGE OF THE YEAR

Probably the most important annual message delivered in the English-speaking world of science—and it is, indeed, eagerly looked for throughout all the scientific world—is the address of the president of the British Association for the Advancement of Science. The annual presidential address was delivered by Professor J. J. Thompson, the distinguished British physicist. The whole address[1] is well worth perusal by physicians who are interested in general science and by educators of all classes, whether especially interested in science or not.

Though far from pessimistic as to the future, Professor Thompson sees in modern education two tendencies which do not favor the development of investigating scientists and original discoverers—or, indeed, of broad and well-balanced men and women. One is the tendency away from the concrete and practical to mere bookishness; the other is the tendency to premature and excessive specialization.

Professor Thompson's experience has taught him that the mental activity required for the supposedly intellectual process of reading may be extremely slight, and the educational value correspondingly small. He says: "It is possible to read books, to pass examinations, without the higher qualities of the mind being called into play. Indeed, I doubt if there is any process in which the mind is more quiescent than in reading without interest. I might appeal to the widespread habit of reading in bed as a prevention of insomnia as a proof of this. But it is not possible for a boy to make a boat or for a girl to cook a dinner without using brains. With practical things, the difficulties have to be surmounted; the boat must be made water-tight; the dinner must be cooked; while in reading there is always the hope that the difficulties which have been slurred over will not be set in the examination."

In the second place, Professor Thompson feels that overspecialization, especially too early in life, can do only harm to the individual—and much more to science itself—by lessening the enthusiasm of the investigator. He says:

"Premature specialization . . . injures the student by depriving him of adequate literary culture, while when it extends, as it often does, to specialization in one or two branches of science, it retards the progress of science by tending to isolate one science from another. The boundaries between the sciences are arbitrary, and tend to disappear as science progresses. The principles of one science often find most striking and suggestive illustrations in the phenomena of another."

Successful research, Professor Thompson believes, requires not merely training, skill, patience and labor, but abounding faith and enthusiasm. His own message is the more valuable, therefore, because he feels that the present is a time of quickening—a Renaissance in science—and that we have left behind the pessimism of twenty years ago, which believed that all the interesting things had been discovered, and that all that was left for science was the dreary task of altering a decimal or two in some physical constant. "There never was any justification for this feeling," he proclaims; "there never were any signs of an approach to finality in science. . . . As we conquer peak after peak we see in front of us regions full of interest and beauty, but we do not see our goal, we do not see the horizon; in the distance tower still higher peaks which will yield to those who ascend them still wider prospects and deepen the feeling, whose truth is emphasized by every advance in science, that 'great are the works of the Lord.' "

THE SURFACE PRIVY AS A FACTOR IN SPREADING HOOKWORM DISEASE AND TYPHOID FEVER

Charles W. Stiles in a recent article[1] calls attention to the faulty disposal of excrement as the chief factor in producing the soil pollution which makes hookworm infection possible. Of 366 farm houses scattered over four southern states, it was found by actual count that only 115 houses, or 31.4 per cent., were provided with privies, while 251 houses, or 68.5 per cent., had no privy. Even when the privy is present it frequently affords little protection against soil pollution, because not properly built or not properly cleaned. The improper construction of the privy favors the spread not only of hookworm disease but of typhoid as well. While the cure of hookworm disease is of vast economic importance for the South, the reform of the insanitary conditions and habits that make this disease possible is of far greater importance, since it means a great lessening of typhoid and other infections, and such reform is applicable to a certain extent to the whole country. As Dr. Stiles says: "To do away with this soil pollution is not only in the interest of the public health, but also in the interest of the further economic development of the South, especially on the farms and in the textile industries." It is to be hoped that the economic argument may so reenforce the sanitary that a genuine reform in the habits of the agricultural population may be effected.

Medical News

CALIFORNIA

New Case of Bubonic Plague.—The second case of plague reported to have developed within two months in Alameda county, has been reported and diagnosed, and the diagnosis has been confirmed by Surgeon Rupert Blue. The patient was a boy who is said to have caught, played with, and ate ground squirrels, which are known to be carriers of the plague. The patient died. The first of the patients from Alameda county died in the County Hospital, August 19.

---

[1] Science, Aug. 27, 1909, new series, xxx, 257.

[1] Public Health Reports, Oct. 1, 1909, xxiv, No. 40.

Personal.—Dr. Charles B. Pinkham has been appointed chief surgeon of the Central Emergency Hospital, San Francisco, vice Dr. Wallace I. Terry, resigned.——Dr. Louis A. Frary has been appointed second assistant physician of the Napa State Hospital, vice Dr. Leonard M. Pulsifer, resigned, and Dr. J. Rodgers, Alameda, has been appointed third assistant physician.——Dr. Frederick W. Reynolds has succeeded Dr. William A. Weldon as surgeon of the Southern Pacific Railroad Company at San Pedro.——Dr. Cullen F. Welty, San Francisco, has returned from Europe.

ILLINOIS

Banquet to Dr. Norbury.—Dr. Frank Parsons Norbury, who has been appointed superintendent of the Kankakee State Hospital, was given a banquet at Jacksonville, October 15, by the Morgan County Medical Society and the Jacksonville Medical Club. The banquet was served at the Pacific Hotel, and Dr. Carl E. Black acted as toastmaster.

State Charities Conference.—At the fourteenth annual session of the Illinois Conference on Charities and Corrections, held in Peoria, October 9-12, William C. Graves, secretary of the State Board of Charities, was elected president; Mrs. Ophelia Amigh, Geneva, vice-president; Sherman C. Kingsley, Chicago, secretary; Ray Arnold, Galesburg, assistant secretary; and F. Emery Lyon, Chicago, secretary of the executive committee. The conference adopted a resolution urging a law for adult probation; the ten-hour day for women in factories; medical inspection of public schools; a large number of parole officers under civil service; establishment of a state epileptic colony; and the observance of the last Sunday in October as Prison Sunday by all religious denominations.

Chicago

Personal.—Dr. Ralph Edward Sheldon, associate in anatomy in the University of Chicago, has been appointed assistant professor of anatomy in charge of histology, embryology and neurology in the University of Pittsburg Medical School.

Delegates to Children's Conference.—The following physicians have been named by the mayor to attend the Conference on the Prevention of Infant Mortality, to be held at Yale University, November 11 and 12, under the auspices of the American Academy of Medicine: Drs. William A. Evans, Isaac A. Abt, Thomas A. Woodruff, Casey A. Wood, Frank X. Walls, Charles R. Henderson, Frank S. Churchill, Caroline Hedger, Joseph Damiani, George C. Hunt, Joseph P. Cobb and Stephen R. Pietrowicz.

KENTUCKY

State Board Changes.—Dr. Joseph M. Mathews, Louisville, who has served eighteen years as president of the State Board of Health, resigned October 18, and the board elected Dr. William Bailey as president. Under the law governing the State Board of Health, the governor must appoint members from a list of three names suggested by the state medical association, and the House of Delegates, at its first meeting, recommended to the governor the names of Drs. Joseph E. Wells, Cynthiana; Isaac A. Shirley, Winchester; and Charles Z. Aud, Cecilian. The board took up the charges against Dr. Melvin Rohrer, Lexington, formerly first assistant superintendent of the State Insane Hospital, for alleged malpractice, and decided that Dr. Rohrer was guilty and revoked his license to practice, and decided to urge the next legislature to enact a law punishing physicians guilty of criminal operation.

State Association Meeting.—At the fifty-fourth annual meeting of the Kentucky State Medical Association, held in Louisville, October 19-21, there were 651 members who registered. The following officers were elected: Dr. Joseph E. Wells, Cynthiana, president; Drs. Philip H. Stewart, Paducah; James O. Carson, Bowling Green; and James S. Lock, Barbourville, vice-presidents; Dr. David O. Hancock, Henderson, orator in medicine; Dr. George A. Hendon, Louisville, orator in surgery; and Drs. Walter F. Boggess, Louisville, and Benjamin F. Van Meter, Lexington, delegates to the American Medical Association. The House of Delegates endorsed the good-road movement in Kentucky and passed strong resolutions against the practice of criminal abortion; endorsing the establishment of a medical department in the State University, petitioning the legislature and board of trustees of the university to provide such means and ways as will establish a new era for higher medical education. Lexington was selected as the place of meeting for 1910.

MARYLAND

Society Meeting.—At the annual meeting of the Washington (D. C.) Clinical Society, at Rockville, October 16, Dr. M. A. Custis was elected president and Dr. J. R. Sharp secretary.

Ladies Entertained.—The Ladies' Auxiliary of the Medical and Chirurgical Faculty of Maryland gave a reception to the ladies of the society at Medical Hall, at which Dr. Eugene F. Cordell, on behalf of the faculty, outlined the plans of the Widow's and Orphan's Home Fund, and spoke on what had been accomplished.

Baltimore

Personal.—Dr. George M. Settle was operated on at University Hospital, October 20, for appendicitis.——Dr. J. Hall Pleasants will spend the winter in the Adirondacks.

Mayo to Lecture.—Dr. Charles H. Mayo, Rochester, Minn., will deliver two lectures on "Diseases of the Thyroid Gland," at the University of Maryland, November 9 and 10. On academic day, November 11, the degree of LL.D. will be conferred on Dr. Mayo by the university.

MASSACHUSETTS

Contagious Disease Hospital.—Both branches of the Cambridge city government gave a hearing October 19, on the question of appropriating $100,000 for a hospital for contagious diseases. The medical inspector of the health board estimated the cost of the proposed building, including two wings, at $80,000.

Elections.—The Massachusetts Society of Examining Physicians held its annual meeting in Boston, October 19, and elected the following officers: President, Dr. Francis D. Donaghue (reelected); vice-presidents, Drs. Frank E. Allard, Edward M. Greene, and Timothy Leary; secretary, Dr. A. Carlton Potter; treasurer, Dr. Henry M. Chase, Jr.; and council, Drs. Frederick M. Briggs, Benjamin Tenney, Edward B. Lane, John L. Ames, and T. J. Hanley, all of Boston.——The Brookline Medical Club has elected the following officers: President, Dr. Henry V. McLaughlin; vice-president, Dr. George W. Kaan, and secretary-treasurer, Dr. H. Hale Powers.——At the annual meeting of Holyoke Medical Society, held October 12, the following officers were elected: President, Dr. Thomas E. Cavanaugh; vice-president, Dr. George D. Henderson; secretary-treasurer, Dr George C. Robert; and executive committee, Drs. George L. Taylor, Joseph H. Potts, and John J. Carroll.

MINNESOTA

Personal.—Dr. George M. Doran, St. Paul, is critically ill in St. Joseph's Hospital, from a bullet wound of the abdomen.——Dr. Charles E. Smith, Jr., has been appointed second assistant physician of St. Paul and Ramsey county, and Dr. Elmer M. Jones has been made first assistant, vice Dr. Adolph Stierle, Jr., term expired.

State Association Meeting.—The annual meeting of the Minnesota State Medical Association was held in Winona, October 12-14. The following officers were elected: President, Dr. William A. Jones, Minneapolis; vice-presidents, Drs. Frank W. Dimmitt, Red Wing; Hugh F. McGaughey, Winona; and Charles W. Bray, Biwabik; secretary, Dr. Thomas S. McDavitt, St. Paul (reelected); treasurer, Dr. Richard J. Hill, Minneapolis; and councilors, Drs. Eugene A. Hensel, Alexandria, Frederick A. Knights, Minneapolis, and Franklin A. Dodge, LeSueur. The 1910 meeting of the association will be held in Minneapolis.

MISSOURI

Personal.—Dr. Arthur B. Freeman has been elected chairman, and Dr. Mary L. Mack, secretary of the Joplin Branch of the Jasper County Medical Society.——Dr. Harold R. Lucas, division and examining surgeon for the Frisco System at Chaffee, has resigned and entered private practice in Joplin. Dr. George A. Sample has been appointed his successor.

St. Louis

Personal.—Dr. Albert E. Taussig has taken charge as editor of the *Weekly Bulletin of the St. Louis Medical Society.*——Drs. H. Jackson Harrell, Martin C. Woodruff and George W. Flinn have been appointed vaccine physicians, and Dr. Fred Gunn has been appointed junior assistant physician at the City Hospital.——Dr. and Mrs. William W. Graves have returned from Europe.——Drs. John McJ. Dean and Louis Rassieur have been appointed surgeons-in-charge of St. Mary's Infirmary, vice Dr. William A. McCandless, resigned.

Proposed Sanitary Ordinances.—The Municipal Commission on Tuberculosis has prepared ordinances providing for the establishment of an emergency hospital for the care of persons afflicted with acute contagious and infectious diseases, and transferring the appropriation for the maintenance of the smallpox and quarantine hospital to the maintenance of this hospital; making provision for the exclusive use of Building "A" of the City Hospital for the care and treatment of advanced cases of tuberculosis; providing for the conversion of the present quarantine and smallpox hospital into a tuberculosis sanatorium; providing for the establishment of two clinics at the eastern ends of the fourth and second sanitary districts for the free treatment of persons afflicted with tuberculosis; providing for the appointment of seven nurses to visit consumptives in their homes; providing for the appropriation of $10,000 for the relief of indigent consumptives; providing for the payment of part of the salaries of city employés while undergoing treatment in the hospital or sanatorium; the abolition of the common drinking cup in the city; providing for the proper ventilation of street cars; providing for the medical inspection of children for the prevention of contagious and communicable diseases, and for the correction of physical defects, and providing that persons afflicted with tuberculosis, applying to the city for treatment in hospitals or dispensaries, or for relief in their homes, shall not be considered as paupers.

NEW YORK

Branch of State Laboratory at Cornell.—A branch hygienic laboratory has been established by the State Department of Health at Cornell University, Ithaca. It is located on the ground floor of Lincoln Hall, and will be in charge of Dean Haskell, and Prof. H. N. Ogden, hydraulic expert for the health department.

District Society Meeting.—The Medical Association of Central New York, held its forty-seventh annual meeting in Auburn, October 19. Dr. Frederick W. Sears, Syracuse, was elected president and Dr. Wesley T. Mulligan, Rochester, vice-president. Dr. Robert T. Morris, New York City, discussed the surgical treatment of appendicitis.

New State Insane Hospital.—A new hospital for the insane is to be established on Lake Mohansic, seven miles from Peekskill, where a site has been purchased for $135,000. The hospital will take care of the overflow of the other New York City and state insane institutions. The buildings are to cost $1,000,000 and will accommodate 2,000 patients.

New York City

The Carpenter Lecture.—Dr. Howard T. Ricketts of the University of Chicago, delivered the Wesley M. Carpenter Lecture before the New York Academy of Medicine, Thursday, October 21, on "Spotted Fever."

Lectures on Skin Diseases.—Dr. L. Duncan Bulkley will give an eleventh course of clinical lectures on diseases of the skin at the Skin and Cancer Hospital on Wednesday afternoons at 4:15, commencing November 3. The course will be free to the medical profession.

Harvey Society Lectures.—The course of lectures of the Harvey Society for 1909-1910 will begin at the Academy of Medicine, October 30, at 8:30 p. m., when Prof. Richard M. Pearce of University and Bellevue Hospital Medical College will read a paper on "The Problems of Experimental Nephritis."

OHIO

State Board Elects.—The Ohio State Board of Health, at its meeting, October 14, elected the following officers: President, Dr. Jefferson C. Crossland, Zanesville; vice-president, Dr. William T. Miller, Cleveland; and secretary, Dr. Charles O. Probst, Columbus.

Personal.—At a meeting of the Lima Antituberculosis League, October 6, Dr. William E. Hover was elected president. ——Dr. Mason O. Wert, Poplar, has started on a trip around the world.——Dr. Joseph A. Murphy has been appointed coroner of Columbus, during the absence of Dr. William F. Bay.——Dr. George S. Weger, Delphos, has been elected a member of the school board.——Dr. and Mrs. Curtis Laughlin, Steubenville, have returned from Europe.

Colleges Open.—The Cleveland College of Physicians and Surgeons, Medical Department of the Ohio Wesleyan University, opened for its annual session, October 11. The following faculty changes were announced: Dr. Roland E. Skeel has been made professor of gynecology; Dr. Arthur J. Skeel, professor of obstetrics; Dr. John F. Davidson, professor of anatomy; Dr. Augustus F. House, clinical professor of surgery; Dr. Harry B. Kurtz, professor of dermatology; Dr. John V. Gallagher, professor of surgery; Dr. Walter B. Laffer, professor of mental and nervous diseases; Dr. Ralph K. Updegraff, associate professor of physical diagnosis; and Dr. Willard C. Stoner, lecturer and demonstrator of microscopy. ——The Medical Department of Western Reserve University opened for its annual session October 1.

Cincinnati

College Opens.—The formal opening exercises of the new Ohio-Miami Medical College were held October 2. The introductory address was given by President Dabney, and Dr. Charles A. L. Reed spoke on "The Modern Medical College."

Personal.—Drs. Woolley and Wherry have been placed in charge of the newly organized department of pathology in the Cincinnati Hospital.——Dr. E. G. Betty has been appointed dental and consulting surgeon at the City Hospital, vice Dr. W. H. Kempton.

PENNSYLVANIA

Aid to the Tuberculous.—*A gift of 450 acres of land was made to the State of Pennsylvania, absolutely free of any incumbrance, for use as the site of a new sanitarium for the gratuitous treatment of tuberculosis patients, October 20, by Mr. Andrew Carnegie, through the State Commissioner of Health, Dr. Samuel G. Dixon.* The land is located at Cresson, Cambria county, and is 2,400 feet above sea level. The tract possesses scenic views unsurpassed by any spot in the state. It is on the main line of the Pennsylvania Railroad and about one hundred miles east of Pittsburg, and, therefore, very acceptable. It is said that the gift will be accepted. Dr. Dixon made a careful inspection of the site October 23.——A site for the Berks County Tuberculosis Sanatorium has been secured by the purchase for $8,000, the Centennial Springs Hotel on the southern slope of the Neversink mountains, and in addition Rev. George Borneman, pastor of St. Paul's Catholic Church, has given the Neversink Hotel property adjoining. ——The grand total of receipts for Tuberculosis Day at Reading amounted to $10,613.20.

Philadelphia

Personal.—Dr. Paul R. Walters has been appointed assistant demonstrator of physical diagnosis and assistant demonstrator of pharmacy and materia medica at Jefferson Medical College.——Dr. Maude M. Rees has been appointed a member of the staff of the State Insane Hospital, Kalamazoo, Mich.

Budget for City Hospitals.—The budget of Dr. Neff for the maintenance of the Philadelphia General Hospital, the Philadelphia Hospital for the Insane, Home for the Indigent, and Philadelphia Hospital for Contagious Diseases, and for the Board of Health amounts to $1,564,831. The committee not only approves the budget, but in place of cutting down any item, added two items to the budget, amounting to $30,000.

Site for Tuberculosis Sanatorium.—The final arrangements for the establishment of a local dispensary for the prevention and cure of tuberculosis, by the recently organized Jewish Consumptive Institute Association, have just been completed by the purchase of a large building at 212 Catherine street. Alterations on the building are to be started at once to make it a modern institution for the treatment of the tuberculous poor.

VERMONT

Society Meetings.—At the ninety-sixth annual meeting of the Vermont State Medical Society, held in White River Junction, October 14 and 15, the following officers were elected: President, Dr. Walter L. Havens, Chester Depot; vice-president, Dr. Edward H. Ross, St. Johnsbury; secretary, Dr. Clarence H. Beecher, Burlington; treasurer, Dr. Bingham H. Stone, Burlington, and auditor, Dr. Anson M. Norton, Bristol. The next meeting will be held in St. Albans. The House of Delegates elected Dr. Archibald J. Valleau, Morrisville, president; Dr. William Lindsay, Montpelier, first vice-president; Dr. Mark R. Crain, Rutland, second vice-president; Dr. Arthur O. Morton, St. Albans, secretary, and Drs. Walter L. Havens, Chester Depot, Clarence H. Beecher, Burlington, and George C. Berkeley, St. Albans, executive committee.——Bennington County Medical Society, at its annual meeting elected Dr. Anselme E. Houle, Bennington, president; Dr. George V. Wager, North Bennington, vice-president; Dr. Lewis H. Hemenway, Manchester, secretary; Dr. Frank W. Goodall, Bennington, treasurer; Drs. Houle, Goodall, and Hemenway, censors; Dr. Hemenway, delegate to the Vermont State Medical Society, and Dr. Lucretius H. Ross, Bennington, alternate.

VIRGINIA

Tuberculosis League Changes Name.—The Tuberculosis League of Lynchburg has decided to change its name to the Health League, and the scope of the organization will be enlarged in keeping with the name. Dr. Ferdinand M. Perrow is president.

County Society Election.—At the annual meeting of the Norfolk County Medical Society, the following officers were elected: President, Dr. Lawrence T. Royster; vice-president, Dr. Israel Brown, and secretary-treasurer, Dr. D. Lee Hirschler (reelected).——Nansemond County Medical Society, at its annual meeting, in Suffolk, October 13, elected Dr. Japheth E. Rawls, Suffolk, president; Dr. Job G. Holland, Holland, vice-president, and Dr. Edward R. Hart, Suffolk, secretary-treasurer.

New Medical Examining Board.—The following members of the examining board of Virginia have been nominated by the Medical Society of Virginia and commissioned by the governor: At Large—Drs. Rawley W. Martin, Lynchburg, Robert B. James, Danville, and John G. Rennie, Petersburg; First District—Dr. Joseph N. Barney, Fredericksburg; Second District—Dr. Herbert Old, Norfolk; Third District—Dr. Junius E. Warinner, Brookhill; Fourth District—Dr. Otho C. Wright, Jarratt; Fifth District—Dr. Richard S. Martin, Stuart; Sixth District—Dr. Henry W. Dew, Lynchburg; Seventh District—Dr. Philip W. Boyd, Winchester; Eighth District—Dr. Robert M. Slaughter, Theological Seminary; Ninth District—Dr. Elliott T. Brady, Abingdon, and Tenth District—Dr. Robert Glasgow, Lexington.

GENERAL NEWS AND COMMENT

Ohio Valley Meeting.—The Ohio Valley Medical Association will hold its eleventh annual meeting at Evansville, Ind., November 10 and 11, under the presidency of Dr. Curran Pope, Louisville, Ky., the subject of whose address will be "The Problem of Living." The membership of the association includes Kentucky, Ohio, Indiana and Illinois.

Pellagra Conference.—The preliminary program of the National Conference on Pellagra, to be held at the State Hospital for the Insane, Columbia, S. C., November 3 and 4, under the auspices of the South Carolina State Board of Health, includes the consideration of the economic problems of pellagra; the etiology, pathology, diagnosis, and treatment of the disease; the theories as to its causation; statistical reports; the spoiled corn hypothesis; whether or not it is contagious; its relation to insanity and to diseases of other organs. A number of cases will be presented, lantern slides will be shown, demonstrations will be made, and the question of a permanent national organization for the study of the disease will be brought up.

The Christmas Stamp.—According to Ernest P. Bicknell, director of the American Red Cross (*The Survey*, Oct. 16, 1909), the sale of stamps last year netted $135,000 for the campaign against tuberculosis. This season the Red Cross will provide a supply sufficient to meet all needs. A new design, the result of a competition among about 1,200 persons, has been adopted and the stamps will be ready for shipment to agent November 1. The stamp, one inch square, will be in red and dark green with lettering in white, and will be sold for one cent. The stamps are to be sold only by recognized and reliable agents and the proceeds must be devoted to anti-tuberculosis work. The stamps, posters, and printed matter intended to assist in the sale of stamps will be supplied to agents free, the agency to return to the Red Cross the unused stamps and one-third of the face value of the stamps sold. (The Red Cross may be addressed at Washington, D. C.) The privilege of selling the stamps in the corridors of the post offices has been granted this year as last.

Southwestern Physicians to Meet.—The annual meeting of the Southwestern Medical Association will be held in San Antonio, Texas, November 9, 10 and 11. At the same time the Fifth District Medical Association of Texas will hold its annual meeting. An excellent program has been prepared and the fraternity of San Antonio are making elaborate preparation for the meeeting. Dr. Malcolm Lasalle Harris, Chicago, will deliver the oration on surgery, and Dr. George Dock, New Orleans, the oration on medicine.

Railway Surgeons Meet.—At the annual session of the American Association of Railway Surgeons, held in Chicago October 21 and 22, the following officers were elected: President, Dr. Henry C. Fairbrother, East St. Louis, Ill.; vice-presidents, Drs. David Y. Roberts, Louisville, Albert R. Mitchell, Lincoln, Neb., and John P. Kaster, Topeka, Kan.; secretary, Dr. Louis T. Mitchell, Chicago (re-elected), and treasurer, Dr. Henry B. Jennings, Council Bluffs, Iowa.——The Association of Seaboard Air-Line Surgeons held its eighth annual meeting in Raleigh, N. C., October 19-21, under the presidency of Dr. Joseph M. Burke, Petersburg, Va., and elected the following officers: President, Dr. James R. Rogers, Raleigh, N. C.; vice-presidents, Drs. Jarvis G. Dean, Dawson, Ga., Hillary M. Wilder, Charlotte, N. C., and Hampden A. Burke, Petersburg, Va.; secretary-treasurer, Dr. Jarrett W. Palmer, Ailey, Ga. (re-elected), and member of executive committee, Dr. Emmett H. Terrell, Richmond, Va. The next annual session will be held in Birmingham, Ala.

CANADA

Hospital Notes.—At the eighteenth annual meeting of the Montreal Foundling and Baby Hospital, the fact was brought out that the death rate in the institution had been materially lessened during the past year, chiefly by a purer milk supply. It had been necessary to refuse 300 children admittance during the year and this emphasized the urgency for a larger institution.——Ingersoll, Ont., has recently opened a new hospital.——The Toronto Western Hospital is erecting a new wing.——In 1908. there were 6,268 patients in the hospitals for the insane in the province of Ontario, an increase of 178 over the previous year.

Tuberculosis Sanatoriums.—The province of Quebec now has completed a provincial sanatorium for the treatment of cases of tuberculosis, situated on Lake Edward, about two hundred miles north of Quebec City on the Quebec and Lake St. John division of the Canadian Northern Railway. It will accommodate thirty patients and has been built at a cost of $35,000. Dr. W. E. Ainley, Lachine, late of the Montreal General Hospital staff, is in charge as medical superintendent. A considerable sum has been subscribed for maintenance by the citizens of the province. No free patients are admitted and the charge of each patient is fixed at seven dollars a week.——During the week ended October 16 the Royal Edward Institute for the Treatment of Tuberculosis was opened in Montreal.

Canadian Medical Association.—The forty-third annual meeting of the Canadian Medical Association will be held in Toronto June 1-4, 1910, under the presidency of Dr. Adam H. Wright, Toronto. Drs. D. J. Gibb Wishart, R. W. Bruce Smith, James F. W. Ross, Allen Baines, Charles J. Hastings, and George Elliott (general secretary), comprise the committee of arrangements. The meetings will be held in the Convocation Hall of the University of Toronto. The executive council met in Toronto October 11 and appointed the following special committee on dominion registration: British Columbia, Drs. Simon J. Tunstall, Vancouver, and James H. King, Cranbrook; Alberta, Drs. J. Kennedy and James D. Lafferty, Calgary; Saskatchewan, Drs. Maurice McD. Seymour, Regina, and William A. Thomson, Regina; Manitoba, Drs. Robert J. Blanchard, Winnipeg, and Robert S. Thornton, Deloraine; Ontario, Drs. Robert H. W. Powell, Ottawa, and Frederic N. G. Starr, Toronto; Quebec, Drs. Emmanuel P. Lachappelle, Montreal, and Herbert S. Birkett, Montreal; New Brunswick, Drs. Murray Maclaren, St. John, and John W. Daniel, St. John; Nova Scotia, Drs. John Stewart, Halifax, and Geo. M. Campbell, Halifax, and Prince Edward Island, Drs. Stephen R. Jenkins, Charlottetown, and James Warburton, Charlottetown. It is expected that the new journal of the association will appear about Jan. 1, 1910.

LONDON LETTER

(From Our Regular Correspondent)

LONDON, Oct. 16, 1909.

Women's Success in Medicine

The winter session of the London School of Medicine for Women has commenced, this being the first time the school has met since the opening to women of the Colleges of Physicians and Surgeons of London. The president, Dr. Garrett Anderson, made the gratifying announcement that of the seven students sent by the school for the first medical examination of the London University (the degree of which stands highest in this country) every one had passed; in the second medical there were 12 passes; 28 had taken the M.B. and B.S. of London; 2 the M.B. of Durham, and 2 the conjoint colleges of Scotland, and 7 former students the M.D. of London. Such a list of successes would be an honor to any medical school.

Heart Overstrain in Athletes

At the opening of the winter session of the Postgraduate College of the West London Hospital, Prof. Theodor Schott of Nauheim delivered a most important address on "Overstrain of the Heart by Athletics." After alluding to the pioneer work of Peacock and to the researches of Myers, Allbutt, Da Costa, Sitz and Münzinger, he said that he reported to a medical congress in Vienna in 1890 experiments he had made to determine whether bodily overstrain could produce alterations in a healthy heart. He selected healthy young subjects at ages ranging from 14 to 32. He had them wrestle and perform other exercises until a high degree of dyspnea was produced, and he found that the heart became temporarily dilated. His observations were confirmed by the *x*-rays. Chronic overstrain he regarded as due to repeated excessive muscular efforts. His views were confirmed by the enlargement of the heart found in bicyclists and ski-runners. Only last year he performed further experiments which showed that a healthy heart hypertrophied from excess of work, such as occurred under excessive indulgence in athletics. Strong emotions, fright or shock also produced serious effects on the heart. Dilatation followed mountain climbing from accumulation of blood in the heart cavities. Experiments on heavily accoutered soldiers who had climbed high mountains with the result that dyspnea was produced, showed that the cardiac diameter was increased 2 or 3 centimeters.

PARIS LETTER

(From Our Regular Correspondent)

Paris, Oct. 8, 1909.

Congress of Surgery

The opening session of the twenty-second French Surgical Congress took place October 4 under the presidency of Dr. Richelot, member of the Academy of Medicine and professor *agrégé* at the Paris medical school. It brought together in addition many Parisian and provincial surgeons, a great number of foreign surgeons, among whom were Professors Czerny of Heidelberg, Kocher of Berne, Gibson of New York, and Jonnesco of Bucharest. Dr. Richelot delivered a very instructive oration on "Simplicity in Surgery." After having reviewed the progress made by surgery since the foundation of the French Surgical Association, twenty-five years ago, the orator showed that there was still no ground for vaingloriousness. Velpeau once said, "If it were not for erysipelas and purulent infections, surgeons would be gods." "Erysipelas and purulent infection have disappeared," said Dr. Richelot, "and I am strongly inclined to believe that we are still men. Surgery, indeed, is always advancing, but there are still many obstacles in its path, especially those due to lack of simplicity—in the first place, lack of simplicity in the operative equipment." He deprecated the multiplication of varied instruments apparently responding to all the needs and facilitating each movement of the operator, down to the smallest details. He has seen surgeons bring with them enormous chests with multiple compartments, and spread astonishing arsenals around them on the tables, and the operation was done with a single little bistoury and small forceps. He has seen gynecologists brandish formidable tools as if they had had nightmares in which the pelvis looked the size of an underground tunnel. Instruments cannot give brains to surgeons. The one who succeeds the best is the one who makes the best use of his fingers and his good sense.

Richelot also criticized the type of surgeon who, away from his elaborately equipped operating-room, consents to take the bistoury in hand only after having had all the furniture and draperies removed, the pictures turned, that is, only after having raised a great deal of dust. Lister, however, affirmed and proved that asepsis was realized between the field of operation, the instruments, and the surgeon's fingers. He added that lately there have been invented various forms of more or less ingenious apparatus for regulating mathematically and invariably the dose of chloroform that the patient is to breathe in a given period and to furnish a definite mixture of air and of chloroform. No doubt such apparatus have their advantages, but the dose of chloroform should be graduated by clinical observation, each patient having his own receptivity, which only skilled and attentive observation can estimate. In regard to the technic of operations, he declared that many surgeons are too much inclined to say "Such is my practice;" "That is the way that I do." This extreme desire to have an individual surgical technic leads to useless complications, and impels leading surgeons sometimes to perpetuate imperfect procedures. This is one of the circumstances which render it so difficult to simplify surgery.

Death of Professor Heurtaux

Dr. Alfred Heurtaux, former professor of clinical surgery in the Nantes medical school, has just died, aged 78. He was one of the most active collaborators on Jaccoud's *Dictionnaire de médecine et de chirurgie pratiques*, for which he wrote the articles on cancer, inflammation, fibromas, cysts, etc. He had been a national associate of the Academy of Medicine since 1901.

Monument to Professor Tillaux

Yesterday the dedication of the monument to the memory of Prof. P. Tillaux took place in the amphitheater of anatomy of the hospitals of Paris. This monument was the last work of the late sculptor Chaplain. It is in marble and represents Tillaux standing, his right hand on a half dissected cadaver, giving his lesson in anatomy. The monument stands in the garden of the amphitheater where Tillaux was director of anatomy before being appointed professor in the medical school.

Pharmacology

CELLASIN

Report of the Council on Pharmacy and Chemistry

Cellasin, a product of Mead Johnson & Co., was the subject of a report by the Council on Pharmacy and Chemistry in The Journal, Sept. 12, 1908. In this report, the Council voted that cellasin be refused recognition on account of the exaggerated chemical and therapeutic claims made for it. The manufacturers having taken issue with these findings, the Council decided to reinvestigate the product, and the matter was referred both to the original investigator (Referee A) who conducted a new series of experiments, and to a second referee (B), not a member of the Council, who investigated the product independently. The reports containing the findings of both these men were submitted to a third referee (C). The report of Referee C was submitted to the Council, together with the reports of Referees A and B and also letters from Mr. John E. Teeple, chemist for Mead Johnson & Co., and Professor Orndorff. The Council voted that all the matter submitted by Referee C should be published in pamphlet form and Referee C's individual report should in addition be published in The Journal. After this had been decided the manufacturers requested that publication be withheld until they had submitted new evidence, a request which the Council voted to grant for a specified time. At the end of this time Referee C submitted to the Council the following recommendation which was adopted and publication of the Cellasin report authorized.

W. A. Puckner, Secretary.

RECOMMENDATION OF REFEREE C

To the Council: The accompanying letter, dated Aug. 13, 1909, from Mr. John E. Teeple, in behalf of Mead Johnson & Co., and addressed to the Secretary of the Council, has been transmitted to me:

> Mead Johnson & Co. have handed me a copy of your letter to them of July 30, stating that further consideration of Cellasin has been postponed until August 15, and have asked me to write you regarding the matter.
>
> I have worked on this subject in conjunction with bacteriologists a considerable portion of the time since I saw you in Chicago in April. I have been attempting to obtain a sterile solution by some means which would not at the same time interfere with the action of any enzyme which might be present.
>
> From my conversation with you and others in Chicago I believed that there was not at present any question regarding the presence or absence of action on sugar, but that the question was now solely whether the action was bacterial or enzyme.
>
> At the outset I assumed it would be comparatively easy to obtain a sterile solution by some means which would not interfere with the enzyme. I have not yet, however, succeeded in getting a satisfactory result. There are certain bacteria present which are evidently spore bearers and which resist any means of sterilizing so far tried, excepting means which would actually destroy enzyme.
>
> More recently, I have been trying the possibility of sterilizing by repeated filtration through Birkhardt filters, but a very large number of filtrations, through a great many filters, with intervals to allow development of spore, has not yet produced a solution which is sterile.
>
> I am at present endeavoring to isolate the bacteria and develop pure cultures and determine whether any of them have the same action on sugar and same resisting powers that the Cellasin itself seems to have.
>
> It seems certain that we have here either an enzyme or a variety of lactic-acid-producing bacteria widely different from commonly known varieties, and much more active and resistant to chemicals than they are.
>
> I expect to pursue this investigation until I can determine exactly what we have. If under these circumstances your committee cares to leave the matter open a little longer, I shall be glad to report to you at frequent intervals just what results are being obtained. My only desire is to determine the exact truth in the matter.
>
> Awaiting your advices, I remain,

Since Mead Johnson & Co. have on the market a product for which they made certain claims, which they are unable to substantiate in their letter of August 13, and as they themselves arrive at the conclusion that "it seems certain that we have either an enzyme or a variety of lactic-acid-producing bacteria widely different from commonly known varieties, and much more active and resistant to chemicals than they are," I would recommend the publication of the report on cellasin.

REPORT OF REFEREE C

Cellasin was submitted to the Council by Mead Johnson & Co., with the claim that it contained starch-converting and fat-splitting enzymes and an enzyme capable of converting sugar into lactic acid, together with small amounts of acetic and other acids. The report of the committee on chemistry showed that, so far as the action on sugar was concerned, these claims were not substantiated by the examinations made by its referee.

In view of the emphatic assertions of the manufacturer that the claims they made for the product were correct, the committee on chemistry again took up the matter, and after further investigation submitted a second report in which it is stated: "We have given an unusual amount of time to the investigation of cellasin and every opportunity has been afforded the firm to substantiate its claims. These claims could not be verified in any samples submitted, and the committee now and finally recommends the adoption and publication of the report."[1]

In the report on cellasin, as published in THE JOURNAL, it was stated that Mead Johnson & Co. claimed that "the action of cellasin on fats, carbohydrates in acid solution is most powerful." This evidently is an error, the word "acid" having been used when "alkaline" was meant. The firm having made no claim as to the activity of the product in *acid* media, this statement in THE JOURNAL should be corrected.

The consulting chemist of the firm, J. E. Teeple, presented arguments (Oct. 13, 1908) to show that the product contained or might contain an enzyme, and transmitted a report from Prof. W. R. Orndorff of Cornell University, who had examined cellasin with reference to its power to produce acid from sugar. Orndorff's experiments showed that the preparation would convert cane sugar into lactic acid when the media were apparently sterile and even in the presence of antiseptics, but apparently he made no examination of the substance itself or of the fermenting solutions for bacteria.[2]

On the receipt of this letter the matter was referred in accordance with the custom of the Council to the original referee (A) for reinvestigation. Referee A went carefully over the ground and reported in substance, that while cellasin has the power of converting sugar into lactic acid,[3] this action is due in the main to bacteria, of which cellasin contains about 500,000 per gram, and that these bacteria increase, *pari passu*, with the formation of acid. He found that when micro-organisms were removed by proper filtration the activity of the product becomes correspondingly decreased.[4]

In addition to the investigation by the referee, the product was referred to a second referee (B). His report confirmed the findings of the first referee.[5]

In accordance with the regular procedure of the Council, the reports of Referees A and B (the latter not a member of the Council) on cellasin, together with a letter, bearing date of Oct. 13, 1908, and signed by J. E. Teeple (consulting chemist, chemical engineer) in regard to the properties and claims made for the product, and accompanying this letter a report by Prof. W. R. Orndorff of Cornell University, were submitted to the third referee (C) for an additional opinion.

The report of Professor Orndorff goes to show that cellasin does possess considerable power of splitting up cane sugar into acid products, but singularly enough the report is lacking in a bacteriologic control of the results obtained. That he attempted to exclude *extraneous* bacteria is indicated by the statement: "Except in cases where antiseptics were used, all apparatus and chemicals were sterilized before cellasin was added." The possibility that *cellasin itself* might contain the responsible bacteria was seemingly excluded by a number of tests in which antiseptics were employed. The report tacitly assumes that the germicidal and antiseptic substance used either killed or held in check such bacteria as might be present, and, while it does not directly assert the presence of a "true enzyme," still it leads to such an inference. Thus, Mr. Teeple, referring in his letter of Oct. 13, 1908, to the tests made by Professor Orndorff and himself, states "that all of the experiments go to show that we have here a true enzyme whose action is roughly proportional to the amount of enzyme present." In these few words a tangible claim is made which must stand or fall with such experimental evidence as has been presented. The report of Professor Orndorff therefore requires particular attention.

In 8 out of the 12 experiments tabulated in the report of Professor Orndorff, phenol (in amounts of 0.03, 0.06 and 0.1 per cent.) was added to the cane-sugar solution clearly for the purpose of inhibiting the growth of bacteria. And yet, no control was made to ascertain whether the bacteria were actually inhibited, although it was noted that an increase in the amount of phenol retarded the reaction. The statement, made by way of comment on the results obtained, that "This retardation of *enzyme reactions* [Italics not in original] in the presence of antiseptics has been frequently observed," shows clearly that the possibility of *bacterial reactions* was entirely lost sight of.

As a matter of fact, Referee C, on repeating the phenol experiments under practically the same conditions as those which obtained in the experiments of Professor Orndorff, obtained an enormous development of bacteria, and as might be expected, a corresponding conversion of cane-sugar into acid products. The details of one experiment will be sufficient.

TEST WITH 0.1 PER CENT. PHENOL

To 392 c.c. of a sterile 2 per cent. solution of rock candy, 8 c.c. of a 5 per cent. solution of phenol was added. To this solution 2 c.c. of sterile normal sodium bicarbonate and 0.8 gm. of cellasin were added, and the whole mixture then incubated. In this, as in all other tests, made by Referee C, the solutions and containers were absolutely sterile, and special care was taken to avoid external contamination. Hence, the bacteria, if any developed, came from but one source—the cellasin.

Agar plates were poured at the times stated, and the kind and number of bacteria were noted. The clouding of the liquid soon indicated a rapid multiplication, and since the titration of a portion of the liquid showed considerable acid production, sterile normal sodium bicarbonate was added to the liquid from time to time, in order to reduce the acidity. The total acidity at the end of 120 hours calculated as lactic acid, corresponded to 5.28 gm. of lactic acid. This result, as well as the bacterial count when compared with the control test given later on, where no antiseptic was used, shows an almost total absence of a supposed antiseptic action. The following table will serve to show the rapid growth of bacteria in this test:

MIXTURE PLATED	NO. BACTERIA PER C.C.
At once.	3,800
8 hours.	8,400
24 hours.	450,000
48 hours.	58,000,000
72 hours.	70,000,000
96 hours.	90,000,000

The obvious conclusion from this experiment is that 0.1 per cent phenol does not inhibit the action of the bacteria contained in the cellasin. It naturally follows that the 0.03 per cent. and 0.06 per cent. phenol would have even less inhibitory action, if any at all.

A similar experiment made with 0.5 per cent. phenol did show a complete inhibition of the growth of bacteria, and, paralleling this, a total absence of conversion of sugar into acid products. Agar plates made daily for a period of nine days showed about 100 colonies on each of the nine days. These were obviously derived from spores present in the cellasin. The spores, though resistant to 0.5 per cent. phenol, were unable to germinate in such a solution, whereas a 0.1 per cent. solution offered no such hindrance. The failure to effect a cleavage of the sugar can mean only one thing—the absence of a "true enzyme."

---

[1] THE JOURNAL A. M. A., Sept. 12, 1908, p. 931.

[2] Mr. Teeple's letter and Prof. Orndorff's report appear on pages 8 and 10 respectively of the pamphlet; this pamphlet may be had on request.

[3] The action of cellasin on a sugar solution is found to be slow at first. The examinations on which the first reports of the referee were based were made after an incubation for not more than 24 hours. The results were negative as to quantitative results. In the subsequent experiments a longer period of incubation gave considerable formation of acid. It is admitted by the manufacturers that the action of cellasin is too slow to be of use as an intestinal enzyme, but is claimed that it is an intracellular enzyme, similar to muscle enzymes, and acts after absorption into the blood. (As appears in Mr. Teeples' letter, page 8, and also report of Referee A, page 13 of the pamphlet.)

[4] Report of Referee A, page 13 of pamphlet.

[5] Report of Referee B, page 15 of pamphlet.

TEST WITH 0.5 PER CENT. SODIUM SALICYLATE

Two experiments of this kind are given by Professor Orndorff, who obtained about the same amount of conversion as with 0.1 per cent. phenol. Any one familiar with the antiseptic action of sodium salicylate would realize, as in the case of phenol, that very little, if any, inhibition of growth might be expected. Nevertheless, one test was made by Referee C under as nearly identical conditions as possible, and the result showed an even greater multiplication of bacteria than in the test with 0.1 per cent. phenol. The acid production corresponded to 3.78 per cent. lactic acid. It is therefore clear that cellasin contains bacteria which can multiply without apparent hindrance in the presence of 0.5 per cent. sodium salicylate, and hence such test can not be taken to indicate the presence of an enzyme other than that connected with the functional activity of the bacteria.

TEST WITH CHLOROFORM

Two tests were also made by Professor Orndorff using chloroform as an antiseptic, but here, as in other experiments, no controls were made. It is commonly assumed that chloroform water is an efficient antiseptic, and it is less generally known that there are bacteria which can thrive under such conditions. Cellasin, it will be seen, affords an interesting instance of this kind.

A number of tests made by Referee C, with varying amounts of chloroform and under varying conditions of agitation, showed an invariable and unhindered multiplication of the bacteria introduced into the sugar solution with the cellasin. One test will be sufficient to substantiate this point.

To 400 c.c. of a 2 per cent. solution of rock candy there was added 2 c.c. of sterile normal sodium carbonate, 40 c.c. of chloroform and 0.8 gm. of cellasin. Sterile conditions obtained as before except for the cellasin. The glass-stoppered bottle containing the liquid was placed on a mechanical shaker in an incubator and constantly agitated throughout the experiment. Sterile normal sodium bicarbonate was added from day to day to maintain an approximately neutral reaction. On titration at the close of the experiment the acidity produced corresponded to 2.88 gm. of lactic acid. The growth of bacteria can be seen from the following table:

MIXTURE PLATED	NO. BACTERIA PER C.C.
At once.	3,000
10 hours.	850,000
24 hours.	2,000,000
48 hours.	87,000,000
72 hours.	150,000,000
96 hours.	200,000,000
120 hours.	300,000,000

The constant presence of an excess of chloroform, therefore, does not materially interfere with the multiplication of the bacteria, and hence the conversion of sugar obtained under such conditions can not be ascribed to an enzyme contained with the cellasin.

TEST WITH HYDROCHLORIC ACID

The patent specifications describe an enzyme which is *indestructible* in a solution of 25 per cent. hydrochloric acid and it further specifies that the ferment has the empirical formula $C_{72}H_{112}N_{18}O_{22}S$. There are no tests, however, with 25 per cent. acid,[6] and only one is given by Professor Orndorff with a concentration one-tenth that specified, and from his results he deduces the conclusion that "cellasin resists the action of 2.5 per cent. hydrochloric acid." This is quite true, but it does not prove that cellasin is an enzyme or even a mixture containing an enzyme. The presence of resisting spores offers an adequate explanation for the subsequent conversion of sugar.

Several tests were made by Referee C by treating 0.8 gm. of cellasin with 10 c.c. of 2.5 per cent. hydrochloric acid for one hour at 24 C., then neutralizing and adding the mixture to 400 c.c. of a 2 per cent. rock-candy solution. In one instance no growth was obtained and no cleavage of sugar resulted. In three other tests multiplication of bacteria occurred, though very slowly in the beginning, and at the same time sugar was split up into acid products. It is clear, therefore, that 2.5 per cent. hydrochloric acid may destroy all of the bacterial spores present in cellasin, but more often, either because of a large number or through mechanical protection, a few survive and slowly develop when placed under suitable conditions, resulting eventually in rapid growth and the conversion of sugar. Professor Orndorff in his experiment obtained complete conversion of the sugar contents, and although he noted "the only effect observed being a retardation of the reaction at the beginning," yet he failed, apparently, to note the significance of that delay.

In another experiment made by Professor Orndorff, the cellasin was digested with 0.2 per cent. hydrochloric acid in an incubator for five days, then neutralized and added to the sugar solution after which acid production was noted though in lessened amount. This test when repeated and controlled bacteriologically by Referee C showed an almost complete destruction of the bacteria present in cellasin. During the first 24 hours following neutralization there was no evidence of bacterial growth and no cleavage of sugar; after two days, however, the few surviving organisms multiplied sufficiently so as to split up the sugar present to a slight extent. At the end of five days the acidity corresponded to 0.9 gm. lactic acid, while the bacterial content was only four million bacteria per c.c., or about the number to be expected in a control at the end of about from 24 to 30 hours. The significant feature, here as in the other case, is the *absence of all signs of acid production prior to the establishment of a rapid multiplication of the bacteria.*

CONTROLS WITH UNALTERED CELLASIN

Since in the foregoing experiments with antiseptics it is apparent that the action of cellasin goes hand in hand with the growth and multiplication of bacteria, it is hardly necessary to show that cellasin when used direct, i. e., without an antiseptic, will give an equally rich bacterial development. One control of this kind, however, may be given. The test was carried out as in the case of the other experiments; 0.8 gm. of cellasin was added to 400 c.c. of a 2 per cent. solution of rock candy, to which was added 2 c.c. of normal sodium bicarbonate, everything being sterile except the cellasin. The liquid promptly became cloudy and the plate counts showed a rapid multiplication. The amount of acid produced corresponded to 5.4 gm. lactic acid. The increase in bacterial contents will be seen from the appended table:

MIXTURE PLATED	NO. BACTERIA PER C.C.
At once.	2,800
9 hours.	23,500
24 hours.	680,000
48 hours.	12,000,000
72 hours.	62,000,000
96 hours.	60,000,000

THE BACTERIAL CONTENT OF CELLASIN

The number of bacteria contained in cellasin is significant. The standard dilution of 0.8 gm. cellasin in 400 c.c. of sugar solution gave counts which averaged about 3,000 bacteria per c.c., or a total of 1,500,000 per gm. of cellasin. At no time did the samples contain less than 150,000 bacteria per gm. of product.

Of still further significance is the fact that one bacterial species predominated in all three samples of cellasin examined. Moreover, this form was present largely in the spore condition, a fact established by heating experiments, as well as by the behavior of the preparation in the presence of phenol and hydrochloric acid.

It should be stated further, that in plating out the various solutions of cellasin, referred to in the preceding tests, invariably one and the same organism was found. Isolated in pure cultures it was found to be a rapid spore producer. Control experiments made with the pure spores gave essentially the same result as with cellasin. The organism in pure culture splits up cane sugar into acid products, and there can be no question as to the part it plays in the so-called action of cellasin.

---

[6] In the earlier consideration of cellasin, the Council having questioned the claim that cellasin was indestructible in 25 per cent. hydrochloric acid, Mead Johnson and Co. submitted, instead, the statement that cellasin is not destroyed by 2.5 per cent hydrochloric acid.

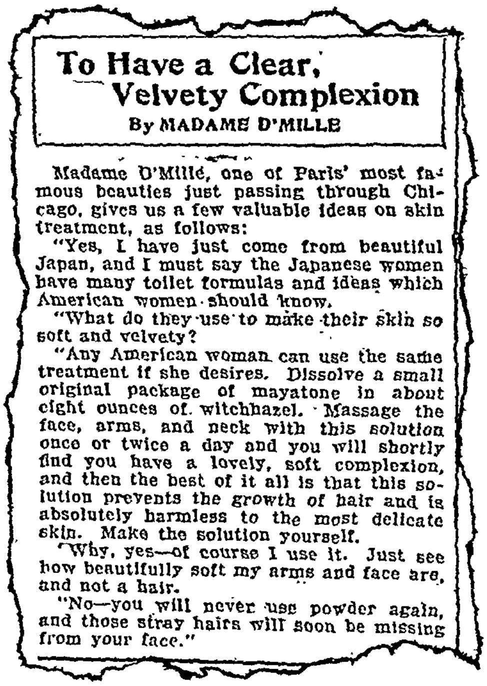
That the action of cellasin depends on the presence and growth of this organism is evident also from filtration experiments. When a solution of cellasin is filtered through a Berkefeld candle into a sterile sugar solution no change whatever results. The solution, after incubation for weeks, remains clear, no acid is produced, and no bacteria can be detected. Were a "true enzyme" present, such would hardly be the case.

The evidence on hand goes to show that cellasin is a mixture of an acid-producing organism and a protein substance, presumably casein. Referee C can, therefore, only confirm the separate findings of Referees A and B, and recommend the rejection of the preparation.

MAYATONE

A French Beauty's Japanese Prescription for American Use

The following advertisement, arranged as reading matter,, has appeared recently in the daily papers:



To Have a Clear, Velvety Complexion

By MADAME D'MILLE

Madame D'Millé, one of Paris' most famous beauties just passing through Chicago, gives us a few valuable ideas on skin treatment, as follows:

"Yes, I have just come from beautiful Japan, and I must say the Japanese women have many toilet formulas and ideas which American women should know.

"What do they use to make their skin so soft and velvety?

"Any American woman can use the same treatment if she desires. Dissolve a small original package of mayatone in about eight ounces of witchhazel. Massage the face, arms, and neck with this solution once or twice a day and you will shortly find you have a lovely, soft complexion, and then the best of it all is that this solution prevents the growth of hair and is absolutely harmless to the most delicate skin. Make the solution yourself.

"Why, yes—of course I use it. Just see how beautifully soft my arms and face are, and not a hair.

"No—you will never use powder again, and those stray hairs will soon be missing from your face."

Mayatone—which is, of course, the "joker" in this "prescription"—is put on the market by the May-a-tone Company of Detroit. It comes in small cardboard packages containing about 2½ ounces of a granular powder, pink in color, and smelling like cheap hair-oil. The price of the package is seventy-five cents. The preparation was examined in the Association's laboratory with the following results:

LABORATORY REPORT

Examination of Mayatone, a product prepared by the May-a-tone Company, Detroit, indicates that the preparation is composed essentially of magnesium sulphate and sodium borate in the following proportions:

Magnesium sulphate (Epsom salts)..............	90 per cent.
Sodium borate (borax)............................	10 per cent.

This analysis confirms the findings of the Kansas State Board of Health, which in its *Bulletin for June, 1909*, reports that Mayatone was "found to be largely magnesium sulphate, perfumed and tinted pink."

The viciousness of such nostrums as Mayatone does not lie in their ingredients but in the dishonest method by which they are exploited. For it is dishonesty, trivial, perhaps, but none the less inherent dishonesty, to attempt by implication or otherwise to make the public believe that a colored and scented mixture of epsom salts and borax is responsible for the "soft and velvety" skin of the Japanese women, and further, that such a "formula" is given to the world through the medium of a Parisian beauty. But the greater dishonesty lies in attempting to make the public believe that the "prescription" or "formula" is given as editorial information, and further that it is composed of non-proprietary articles to be had in any drug store. This form of deception is becoming increasingly common, a fact that reflects little credit on the daily press, whose cooperation makes the humbug possible. It is but fair to say, however, that newspapers of the better type will not lend their pages to this bald attempt to deceive their readers.

Committee on Credentials and Arrangements for Pharmacopeial Convention

President Horatio C. Wood has appointed the following committee on credentials and to make arrangements for the United States Pharmacopeial Convention which will be held in Washington, D. C., beginning Tuesday, May 10, 1910. Prof. O. T. Osborne (chairman), Yale University, New Haven, Conn.; Dr. H. C. Wood, Jr., University of Pennsylvania Medical Department, Philadelphia; Mr. L. S. Hilton, Washington, D. C.; Mr. W. L. Cliffe, Philadelphia.

The following officers of the convention are ex-officio members of the committee: President Dr. H. C. Wood, Jr., University of Pennsylvania Medical Department, Philadelphia; Secretary Dr. H. M. Whelpley, Washington University Medical Department, St. Louis; and Assistant Secretary Dr. Murray Galt-Motter, Hygienic Laboratory, Washington, D. C.

Correspondence

A Visit to the Pellagrosarium at Rovereto

To the Editor:—A news item in THE JOURNAL and Professor Mark's book on the "Skin Changes in Pellagra," induced me to include Rovereto in a recent tour of Europe. The visit was most profitable, and, particularly in view of the interest in pellagra in this country, I have thought it worth while to publish a short account of it.

Rovereto is a city of 11,000 inhabitants, on the *Sudbahn* (southern road) between Trent and Verona. It may easily be reached from Italy or Germany, as through trains from Berlin and Munich to Verona stop there. It is near the romantic Lake Garda and not far from the southeastern high Alps. It can also be reached in what I found a most interesting way, from the region of the Stelvio Pass, by coach and automobile from Madonna di Campiglio, going through the wild and picturesque gorges of the Sarca and rounding the snow-capped peaks of the Brenta. The city lies in the wide Val Lagarina, through which the Adige runs, the torrential Leno entering the Adige a short distance from the city. The valley is surrounded by picturesque mountains covered with vineyards, among which numerous small and characteristic villages are scattered. The city itself possesses many objects of interest, including a well-preserved medieval castle, an interesting town hall, and numerous churches and monasteries. The city once belonged to Venice, and the names of streets and squares still indicate the relationship. It is also said that the fine appearance of the inhabitants—and especially the women—and a certain genial dignity of manner, are survivals of the Venetian period. Rovereto in situation reminds one of Meran. Like the latter, Rovereto is frequented as a winter resort, and also in the fall as a "grape-cure." Snow falls only a few days every year, and a freezing temperature is rarely reached.

Pellagra has long been known in the region of Rovereto; in fact, Dr. de Probizer has recently called attention to the excellent work done in 1822 by Dr. Peter Stofella, a Roveretan, and father of the well-known E. Stofella, who will be remembered by many American students in Vienna. Ever since the Austrian government took up the campaign against pellagra, Southern Tyrol has been included in the work. In 1895 a pellagrosarium was arranged in an old building, which in 1903 was replaced by a new one built especially for the purpose. On presenting myself I was most kindly received by Dr. Bresadola, city physician, and Dr. de Probizer, director of the pellagrosarium; and I was given every facility for seeing patients and other matters of interest.

The hospital is a large two-story building, on a hill overlooking the city, though only a few minutes' walk from the center of the town. It is well-planned and all the details are modern and complete. The large plot of ground around the hospital is being graded and covered with landscape gardening and plantations of vegetables and fruits.

As it was the off season, there were only twenty-five patients in the hospital. The yearly attendance is about 150. On account of the season, also, there were no very severe cases, but the patients were clinically all the more interesting for that reason. Only two or three had any skin changes at all and these were very slight, though in two the process had been more severe in the spring; but I was told that the skin changes were by no means always present and that in fact, since Dr. Merk did his work, there had been no such interesting material as he described. Many of the patients had gastro-intestinal disturbances of rather a mild type; some had evidences of mild stomatitis; several had a peculiar tongue which the doctors told me was quite characteristic, though of course not uniform. In these cases the tongue was not enlarged, the epithelium slightly thin but not stripped, the surface of the tongue wrinkled and the epithelium having a rather unusual, pale violet color. The Italian doctors call this a "raspberry tongue," which of course is not to be confused with what is called a "raspberry tongue" in America. Some of the patients were constipated. Most of them had distinct nervous symptoms, although in many cases these symptoms were so slight that I think the anomaly would be impossible to recognize by one incapable of questioning the patients in their own dialect. Many had the appearance of mild neurasthenics, such as are commonly seen, especially in the middle west, among farmers, and often associated with gastric or sexual symptoms. When I mentioned this to Dr. de Probizer, he said it was quite true, but that his patients did not present the other features of neurasthenia, and especially did not have the characteristic history. Most of these patients were improving.

The treatment is chiefly general, with diet, baths, fresh air and medication only for particular symptoms, as iron or arsenic for anemia. When I mentioned the severe cases, such as have been so noticeable of recent years in the south, and the apparent contradictions of some members of the family having severe pellagra and others exposed to the same causes escaping, the doctors told me that that was exactly what was to be expected when pellagra occurred in a new vicinity. The predisposition, they say, varies extremely, so that one member of the family might acquire the disease and the others, though living in the same way, escape. As the disease becomes more common, and especially when it is present long enough for a predisposition to be acquired by heredity, members of the family are more generally affected, though the disease is likely not to be so severe.

The Rovereto doctors are thoroughly convinced that the cause of pellagra lies in maize. They do not venture to say what the material is, and are not at present making investigations in that direction. When I mentioned typical cases, such as I saw with Dr. Bass, in which the patients made apparently a perfectly credible denial of maize-eating, they said there was no reason why that should not be so, but in their own observation such cases did not occur. Their patients all eat corn, but not, as among the maize-eaters in the south, in the form of corn-bread. They told me that corn-bread should not be capable of producing pellagra. As they find it, it occurs in people who eat "polenta," which corresponds to our corn-meal mush. Properly prepared, this should be cooked for a half-hour, but as a matter of fact it is often imperfectly cooked. The corn concerned in these cases is not raised in the district. Very little maize is raised in southern Tyrol, and the maize in the neighboring Piedmont does not get into the markets. The maize comes chiefly from Roumania and La Plata, and from both of these places often comes obviously moldy. Besides having fed on the diseased maize, the pellagra sufferers are often underfed; sometimes they eat only polenta, and not enough of that. They have also often gone without salt in their food. Other causes considered of importance are alcoholism and syphilis; in fact, in many of the cases, the symptoms of alcoholism were difficult to distinguish from those of pellagrous nervous symptoms.

The treatment of patients in the pellagrosarium is only a small part of the movement against pellagra. The institution serves as a center of statistical, prophylactic and therapeutic effort. Lectures are given, illustrations of the disease are shown, the raising and preparation of maize for food are described, the characteristics of healthy and diseased maize shown by a large collection of specimens. There is maize inspection all over the district. The patients in the institution are taught the advantage of mixed diet, and part of the hospital grounds is used to teach the methods of raising various fruits and other food materials, in order to encourage peasants to introduce these on their own farms. They are even permitted to work on the plantations, provided their conditions permit. The free distribution of salt to those who need it is one of the numerous details carried out. Every doctor in the district assists in keeping up a pellagra census. Every patient discovered is investigated and his data written out on a history sheet printed for the purpose. The finding of one patient is followed by an investigation of all the relatives, and all the findings are written out and the histories sent to the pellagrosarium, where they are filed according to district. Every year a report is made on each case, so that the outcome is constantly known. Although the Rovereto pellagrosarium is not arranged for extensive scientific investigations, a great deal of most excellent work is done there every year. Unfortunately for most of us the publications are almost inaccessible, inasmuch as they are printed in Italian, the language of the district. The yearly "Reports" of the work of the pellagrosarium are very well done. Other clinical and general articles are published as official documents, and still others are published in the *Atti d. i. r. Accad. di Scienze, Lett. ed Arti degli Agiati in Rovereto*, a most creditable publication, reflecting the general high standard of scientific interest in the community.

George Dock, New Orleans.

The Sections and the U. S. Pharmacopeia

To the Editor:—In The Journal, September 4, pp. 791, 793, 796., there were published reports of three committees on the revision of the U. S. Pharmacopeia, namely those of the committees of the Sections on Practice of Medicine, on Ophthalmology and on Stomatology.

There are certain features in these reports well worthy of careful consideration and as they appeared at a time when many physicians had not returned from their vacation I am taking the liberty of calling attention to a few points. These committees were appointed to the sections at the request of the Committee on the U. S. Pharmacopeia of the American Medical Association. The latter committee was appointed by the Board of Trustees at the direction of the House of Delegates in compliance with a recommendation of the Section on Pharmacology and Therapeutics. This committee felt that it could best fulfil the purpose for which it was appointed by ascertaining the attitude of physicians toward the admission to and omission of articles from the Pharmacopeia, and it believed that this could best be accomplished by appealing to the various sections of the Association.

The reports of the committees should be read in their entirety, but it may be worth while to call attention in this place to a few points:

1. *Committee of the Section on Practice of Medicine.*—It should be noted that this committee believes that the present attitude of the U. S. Pharmacopeia toward permanently controlled substances (i. e., proprietaries) should be maintained, namely, that they should not be admitted.

Admissions: The following articles are recommended for admission:

Calcium lactate
Phenolphthalein
Arsenic preparations suitable for hypodermic injection; perhaps sodium cacodylate and sodium arsanilate
Theobromin and theobromin-sodio-salicylate
Bile salts
Diacetyl-morphin

Omissions: Fifty-one drugs and their preparations are recommended to be omitted (THE JOURNAL, Sept. 4, p. 792).

2. *Committee of the Section on Ophthalmology.*—This committee states that it considered the admissions and omissions from the purely ophthalmic standpoint. The committee selected fourteen drugs which they thought might profitably be considered for inclusion in the Pharmacopeia. These were submitted to the members of the Section with the request that each indicate the six which he considered the most important. The six receiving the largest number of votes were:

Adrenalin hydrochlorid
Dionin
Argyrol
Fluorescein
Protargol
Holocain hydrochlorid

A point of special interest in this report is that nearly all of the drugs on which a favorable report is made are proprietary. Whatever may be the attitude of the next Revision Committee toward proprietary medicines, such a report as this shows the serious consideration which they must receive.

Omissions:

Argenti nitras mitigatus
Oleate of cocain
Oleate of atropin
Salicylate of physostigmin
Extractum scopolæ
Extractum stramonii

3. *Committee of the Section on Stomatology.*—This Section makes the following recommendations:

Admissions:

Liquid nitrous oxid
Liquid oxygen
Novocain
Suprarenal alkaloid
Protein silver compound
Magnesium dioxid
Sodium perborate
Perhydrol
Trioxymethylen
Veroform (or a similar solution of formaldehyd)
[illegible]
[illegible]

The list of drugs recommended for admission by this committee is larger than that of the other committees, but any one reading this splendid scientific report must feel that it is written by men who know whereof they speak and that these drugs (or their equivalents) represent real needs. A very significant feature of this report is a brief resolution which the committee requested the Section to adopt. This resolution points out that the present constitution of the Pharmacopeial Convention makes no provision for representation of the dental profession and requests that provision be made whereby the Section on Stomatology of the American Medical Association shall be entitled to representation on the Committee of Revision.

The more carefully these reports are studied the more food for thought they are found to contain. It is not possible or desirable to discuss them at present. One point should, however, be mentioned: There is nothing in these reports to indicate that representative medical men feel a need for the complex proprietary mixtures with which the American market is flooded, a supposed need which the last Committee of Revision endeavored to meet by the inclusion of a number of formulas for similar mixtures. Another point worthy of consideration is the number of preparations recommended by these committees for omission from the Pharmacopeia which were admitted only in the last revision (which appeared in 1905). The most reasonable explanation of this is that the last Committee on Revision was not sufficiently well informed as to the wishes of the medical profession as to the scope of the Pharmacopeia. Finally, the resolution suggested by the Section on Stomatology (that the dental profession be entitled to representation on the Committee of Revision) brings up the large question whether the basis of representation in Pharmacopeia matters is not very far from just. Every incorporated college of medicine and of pharmacy, the incorporated state medical and pharmaceutical societies and certain other bodies are entitled to representation, but the great American dental profession—the profession which gave the world the first general anesthetic, for example—is not given any representation whatever. (In this connection it may also be pointed out that veterinary medicine also receives no recognition by the U. S. Pharmacopeia, although its needs are recognized by the Food and Drugs Act and by most foreign pharmacopeias).

REID HUNT, Washington, D. C.

A Protest Against the Arrogant Surgeon Specialist

To the Editor:—I wish to express my views in regard to the present agitation which is being voiced by some of our older practitioners with reference to a special course in surgery for younger men. I at least have the courage of my opinions and in justice to myself and many others engaged in general practice who are called on to do surgery when occasion arises to call a halt on the so-called specialists in surgery, who wish to claim the field entirely for themselves, and on one plea and another enter a protest of incompetency against their competitors.

What right may I ask has any one engaged in the practice of medicine or surgery to say how much the other man shall do, or not do? Are we not all licensed under the same state laws and are not our qualifications equally as valid as the men who wish to dictate how a man should be specially qualified to do an abdominal section. As a matter of fact, with the exception of the mechanical dexterity acquired by practice, the balance is in favor of the younger man. He has the advantage of a higher education and a better and longer training.

Most of the men who value their opinions to-day as something very superior to that of the younger men, lack the saving grace of even a good high school education and I venture to say that if these men were called on to take a state board examination such as are now being held in several states, would make a sad failure of it.

I have no doubt that at the present day there is much more competition and younger men do as much of their surgery as they can without calling in the old timers, or seek the advice of men of their own class or years, and hence the outcry, but "Time and tide waits for no man."

Every one has the same opportunity and it depends largely on the personal equation as to what advantage is taken of it. The mere fact that a man has had an extra year as an interne in a large hospital does not make him a surgeon any more than the man after graduation who is on his own hook for the same length of time in a general practice; of the two the latter has at least self reliance—and has learned to think and act for himself, he is practically that much ahead of the other fellow.

C. VAUGHAN, Detroit.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

PHYSIOLOGIC ACTION OF CALCIUM LACTATE

To the Editor:—A case of epilepsy treated by calcium lactate is reported in THE JOURNAL, Aug. 14, 1909, p. 527. I have not been able to find any literature on the physiologic action of this salt. I would be thankful to have you describe its action in Queries and Minor Notes.

HUBERT H. JOHNSON, Salinas, Mex.

ANSWER.—The calcium salts appear to increase the energy of the heart's action; the presence of calcium in the nourishing liquid is absolutely essential for the continuance of cardiac action, not only in cold but also in warm blooded animals. Calcium in small doses stimulates both voluntary and involuntary muscles. In small doses calcium chlorid increases the functional activity of the motor nerve trunks, but in large doses it paralyzes the cerebral cortex, the motor centers of the spinal cord and the motor nerve trunks. Calcium salts are essential to the process of coagulation of the blood It is claimed that calcium chlorid and calcium lactate increase the coagulability of the blood for which reason they have been used to prevent hemorrhage. Recent investigations seem to prove that it is not possible to shorten coagulation time by the calcium salts. The question as to their employment for this purpose is therefore *sub judice* (see editorial in THE JOURNAL, March 6, 1909, p. 788, also Addis, T.: *Quart. Jour. Med.*, January, 1909, also *Quart. Jour. Exper. Physiol.*, 1908, 1, 305, Abstr. in THE JOURNAL, April 17, 1909, p. 1283).

Dr. Robert Wells Library
[illegible] Medical College

According to J. D. Zoethout (*Amer. Jour. Physiol.*, February, 1909. abstr. in The Journal, March 27, 1909, p. 1060), calcium favors the relaxation of potassium contraction. MacCallum and Voegtlin (*Jour. Exper. Med.*, 1909, xi, 118) have found that the nerve manifestation of tetany can be held in check by the administration of calcium salts.

In animals after parathyroidectomy there occurs an increased elimination of calcium in the urine and feces which results in a marked reduction of calcium content of the blood and brain and the consequent development of hyperexcitability of the nerve cells. The lack of calcium may therefore be one of the causes of epilepsy and suggests the reason for the use of these salts in that disease. It is believed that disturbances in the calcium metabolism are closely connected with abnormalities of the ductless glands, thyroid, pituitary, etc. (W. B. Bell and P. Hick, *Brit. Med. Jour.*, Feb. 27, 1909).

The action of the lactate of calcium is similar to that of the chlorid but it is less irritating and therefore it may be used hypodermatically.

WANTED: OUTDOOR WORK-CURE SANITARIUM FOR ALCOHOLISM

A correspondent in the middle west asks us where there is a sanitarium—perhaps on a large farm—where a man of 40, who has a cultured mind and a vigorous physique, would receive scientific treatment for alcoholism, together with physical work and mental diversion. Perhaps some of our readers can make suggestions.

ALCOHOL STRENGTH FOR CLEANING HANDS

To the Editor:—In scrubbing the hands preparatory to doing an operation, after the use of soap and water for ten minutes, what strength alcohol should be used, 70 per cent. or 95 per cent.?

E. L. C., New York.

Answer.—Alcohol of 70 per cent. strength should be used because the 95 per cent. alcohol coagulates albumins to such an extent as to nullify the purpose for which it is used—to free the skin of fats in which germs may be encased.

The Public Service

Medical Department of the Army

Changes for the week ended Oct. 23, 1909:

Blanchard, R. M., capt., granted sick leave of absence for 1 month.

Davidson, W. F., capt., granted leave of absence for 1 month.

Wison, J. S., major, ordered to Alcatraz Island, Cal., for duty at the Pacific Branch, U. S. Military Prison.

Thornburgh, R. M., capt., relieved from duty at the Pacific Branch, U. S. Military Prison, Alcatraz Island, Cal., and ordered to the A. G. Hospital, San Francisco, for duty.

Winter, F. A., major, relieved from duty at Fort Myer, Va., and ordered to duty in the office of the Surgeon-General.

Hoff, J. Van R., col., relieved from duty as chief surgeon, Dept. of the Lakes, to take effect on the relief of Col. Charles B. Bryne, M. C., from duty as chief surgeon, Dept. of the East; will then proceed to Governor's Island, N. Y., for duty as chief surgeon, Dept. of the East.

Fuller, L. A., major, granted leave of absence for 14 days.

Raymond, T. U., major, granted leave of absence for 1 month and 15 days.

Heysinger, J. D., capt., granted leave of absence for 1 month.

Marvin, M. F., M. R. C., honorably discharged from the Service of the United States, his services being no longer required.

Adams, P. A., M. R. C., ordered to active duty; will proceed to Schofield Barracks, H. T., for duty.

Holmes, T. G., M. R. C., granted leave of absence to December 15, and honorably discharged from the Service on that date.

Cole, Blase, M. R. C., ordered to active duty; will proceed to Fort Crock, Neb., for duty.

Flynn, T. J., M. R. C., ordered to active duty; will proceed to Fort Ethan Allan, Vt., for duty.

Pinquard, Jos., M. R. C., granted sick leave of absence for 4 months.

Pargon, J. A., M. R. C., honorably discharged from the Service of the United States, his services being no longer required.

Drake, P. G., M. R. C., granted leave of absence for 1 month.

Bailey, Edward, M. R. C., order for Philippine Service revoked.

Freeland, H. L., M. R. C., relieved from duty at Fort Leavenworth, Kan.; will proceed to San Francisco, and sail December 6th for Philippine Service.

Medical Corps of the Navy

Changes for the week ended Oct. 23, 1909:

Shippen, L. P., asst.-surgeon, on reporting at the Navy Department ordered to the Navy Yard, Portsmouth, N. H., for duty at the Naval Prison.

Camerer, C. B., acting asst.-surgeon, appointed acting assistant-surgeon, ordered to instruction at the Naval Medical School, Washington, D. C.

Pryor, J. C., surgeon, detached from command of the Naval Hospital, Yokohama, Japan, and ordered home in the United States, via Europe, with permission to delay 3 months en route.

Bogert, E. S., Jr., surgeon, detached from the Navy Yard, New York, N. Y., and ordered to command the Naval Hospital, Yokohama, Japan.

Foster, T. G., asst.-surgeon, detached from duty at the Naval Prison, Navy Yard, Portsmouth, N. H., granted leave until November 15, on completion thereof ordered to Washington, D. C., for examination and then to wait orders.

Leach, P., medical inspector, detached from command of the Naval Hospital, Newport, R. I., granted leave for 1 month, and on expiration thereof ordered to command the Naval Hospital, Las Animas, Colo.

Hibbett, C. T., medical inspector, detached from command of the Naval Hospital, Las Animas, Colo., and ordered home to wait orders.

McCormick, A. M. D., surgeon, ordered to duty at the works of the General Electric Company, Schenectady, N. Y.

Hathaway, G. S., P. A. surgeon, detached from the *Cheyenne* and ordered to duty in connection with the fitting out of the *New Orleans* and to duty on board that vessel when commissioned.

Public Health and Marine-Hospital Service

Changes for the seven days ended Oct. 20, 1909:

Kerr, J. W., asst. surgeon-general, and Lavinder, C. H., P. A. surgeon, detailed to represent the Service in a National Conference on Pellagra, to be held in Columbia, S. C., Nov. 3-4, 1909.

Woodward, R. M., surgeon, granted 14 days' leave of absence from Oct. 16, 1909, on account of sickness.

Robertson, H. M., P. A. surgeon, leave granted for 2 months from Oct. 1, 1909, amended to read 2 months from Oct. 4, 1909.

Roberts, Norman, P. A. surgeon, granted 2 days' leave of absence from Oct. 13, 1909, under Paragraph 191, Service Regulations.

Sweet, E. A., P. A. surgeon, Bureau order of Oct. 12, 1909 suspended.

Sweet, E. A., P. A. surgeon, directed to accompany a deported alien leper sailing from New York, Oct. 20, 1909.

Frost, W. H., P. A. surgeon, granted 9 days' leave of absence from Oct. 23, 1909.

Ashford, F. A., P. A. surgeon, Bureau order of Oct. 12, 1909 suspended.

Wollenberg, R. A. C., asst.-surgeon, leave granted for 2 months from Sept. 10, 1909, amended to read 2 months from October 6. 1909.

Kolb, L., asst.-surgeon, relieved from duty at Baltimore, and directed to proceed to the Reedy Island Quarantine Station and report to the Medical Officer in Command for duty and assignment to quarters.

Barnes, W., acting asst.-surgeon, granted 30 days' leave of absence from Nov. 1, 1909.

Bean, L. C., acting asst.-surgeon, granted 5 days' leave of absence from Oct. 23, 1909.

Curley, C. P., acting asst.-surgeon, leave granted for 21 days from Sept. 25, 1909, amended to read 16 days from Sept. 21, 1909.

Delgado, J. M., acting asst.-surgeon, granted 22 days' leave of absence from November 5, 1909.

Fisher, C. E., acting asst.-surgeon, granted 16 days' leave of absence from Oct. 15, 1909.

Gustetter, A. L., acting asst.-surgeon, leave granted for 5 days from Oct. 13, 1909, amended to read 5 days from Oct. 16, 1909.

Kimmet, W. A., acting asst.-surgeon, granted 30 days' leave of absence from Oct. 15, 1909.

Onuf, B., acting asst.-surgeon, granted 4 days' extension of annual leave from Oct. 5, 1909, on account of sickness.

Onuf, B., acting asst.-surgeon, granted 23 days' leave of absence from Oct. 21, 1909.

Wise, A. H., acting asst.-surgeon, granted 15 days' leave of absence from October 16, 1909.

APPOINTMENT

Dr. Clifton R. Wallace, appointed an Acting Assistant Surgeon, for duty at Norfolk, Va

RESIGNATION

Acting Assistant Surgeon A. H. Wise, resigned, to take effect Oct. 31, 1909.

BOARD CONVENED

Board of medical officers convened to meet at Seattle, Wash., Oct. 16, 1909, for the purpose of examining an alien. Detail for the board: Passed Assistant Surgeon M. W. Glover, chairman; Assistant Surgeon C. W. Chapin; Acting Assistant Surgeon F. R. Underwood, recorder.

Health Reports

The following have been reported to the Marine-Hospital Service, during the week ended Oct. 22, 1909:

SMALLPOX—UNITED STATES

District of Columbia: Washington, Oct. 2-9, 3 cases.
Indiana: Fort Wayne, Sept. 18-Oct. 2, 15 cases.
New York: Buffalo, Oct. 2-9, 1 case.
North Carolina: Charlotte, Oct. 1-8, 3 cases.
Ohio: Cincinnati, Oct. 2-9, 1 case; Dayton, 1 case.
Oklahoma, general. Aug. 1-31, 18 cases.
Wisconsin: La Crosse, Oct. 2-9, 1 case.

SMALLPOX—FOREIGN

Canada: Hamilton, Sept. 1-30, 2 cases.
Gibraltar, Sept. 19-26, 2 cases.
India: Calcutta, Aug. 21-Sept. 4, 2 deaths; Madras, Sept. 4-10, 1 death; Rangoon, Aug. 28-Sept. 4, 1 death.
Italy: Genoa, Sept. 1-30, 7 cases; Naples, Sept. 26-Oct. 2, 17 cases, 4 deaths.
Java: Batavia, Aug. 21-28, 4 cases, 1 death.
Malta, Sept. 4-11, 2 cases.
Mexico: Veracruz, Sept. 26-Oct. 3, 1 case, 1 death, imported.
Portugal: Lisbon, Sept. 11-25, 13 cases.
Russia: Moscow, Sept. 11-25, 7 cases, 2 deaths; Odessa, Sept. 18-25, 2 cases, 1 death; Riga, 2 cases; Warsaw, Aug. 14-28, 2 deaths.
Spain: Valencia, Sept. 18-25, 1 case; Vigo, 1 death.
Turkey: Smyrna, Aug. 5-Sept. 17, 79 deaths.

YELLOW FEVER

Brazil: Para, Sept. 11-25, 4 cases, 2 deaths.
Ecuador: Guayaquil, Sept. 11-18, 3 deaths.

CHOLERA—INSULAR

Philippine Islands: Manila, Aug. 28-Sept. 4, 8 cases, 6 deaths; Provinces, 201 cases, 114 deaths.

CHOLERA—FOREIGN

China: Hankow, Aug. 21-28, 1 case.
India: Bombay, Sept. 7-14, 22 deaths; Calcutta, Aug. 21-Sept. 4, 10 deaths; Rangoon, Aug. 28-Sept. 4, 3 deaths.
Japan: Kobe, Sept. 6, 3 cases, 1 death.
Korea: Seoul, Sept. 23, present.
Netherlands: Hansweert, Sept. 27-29, 2 cases; Lobik, 1 case.
Russia, general, Sept. 18-Oct. 1, 1,365 cases, 587 deaths; St. Petersburg, 510 cases, 201 deaths.

PLAGUE—INSULAR

Hawaii: Hilo, Sept. 19, 1 case, vicinity.

PLAGUE—FOREIGN

Chile: Iquique, Sept. 8, 2 cases in lazaretto.
Ecuador: Guayaquil, Sept. 11-18, 11 deaths.
India, general, Aug. 21-28, 2,297 cases, 1,811 deaths, Aug. 28-Sept. 4, 2,837 cases, 1,852 deaths; Bombay, Sept. 7-14, 9 deaths; Calcutta, Aug. 21-28, 16 deaths; Rangoon, Aug. 28-Sept. 4, 7 deaths.
Indo-China: Saigon, Aug. 21-Sept. 4, 15 cases, 14 deaths.
Japan: Kobe, Sept. 4-11, 7 cases, 6 deaths.
Peru, general, Aug. 20-27, 16 cases, 12 deaths.

Medical Economics

THIS DEPARTMENT EMBODIES THE SUBJECTS OF ORGANIZATION, POSTGRADUATE WORK, CONTRACT PRACTICE, INSURANCE FEES, LEGISLATION, ETC.

POSTGRADUATE COURSE FOR COUNTY SOCIETIES

DR. JOHN H. BLACKBURN, DIRECTOR
BOWLING GREEN, KENTUCKY

[The Director will be glad to furnish further information and literature to any county society desiring to take up the course.]

Third Month: "The Exanthemata"—First Weekly Meeting

ANATOMY OF THE SKIN

Epidermis, stratum corneum, stratum lucidum, stratum granulosum, stratum mucosum. Corium. Pars papillaris, pars reticularis. Subcutaneous layer. Blood vessels, lymph vessels, muscles, glands, appendages.

PHYSIOLOGY OF THE SKIN

Protective function, heat-regulation, tactile and pain sensations, respiratory and secretory functions, elimination.

MEASLES (RUBEOLA)

Period of incubation, mode of infection, duration of infection. Symptoms, period of invasion, prodromal rashes. Eruptive period, character of eruption, varieties of eruption, desquamation. Complications. Throat, larynx, lungs, digestive system, nervous system, ears and eyes.

Prognosis. Age and condition of patient, season, character of epidemic, complications.

RUBELLA (GERMAN MEASLES)

Symptoms. Period of incubation. Invasion. Eruption, character and variations, desquamation. Diagnosis and differentiation from measles and scarlet fever.

REFERENCE BOOKS FOR THE THIRD MONTH

Welch and Schamberg: Acute Contagious Diseases.
Schamberg: Skin and Infectious Diseases.
Abbott: Hygiene of Transmissible Diseases.
Fox: Smallpox.
Text-books on Pediatrics and on Practice of Medicine.

Treatment of Pellagra.—Acting Assistant Surgeon Moorer (*Public Health Reports*, Oct. 15, 1909) states that he has had during the past five years six cases of pellagra under his observation at the Georgetown, S. C., infirmary. The majority of the cases were in negroes between the ages of 20 and 40. Five patients have completely recovered, the fate of the sixth, who was sent to the state insane asylum being unknown to him. The treatment employed in these cases was strychnin, arsenic and tincture of iron in large and increasing doses, and a strict dietary of two or three quarts of milk with from eight to ten raw eggs a day.

Marriages

DAVID HENRY, M.D., to Miss Anna K. Lechell, both of Philadelphia, October 27.

J. D. LEONARD, M.D., to Miss Margaret Smith, both of Bristol, Tenn., October 4.

ASBURY HULL, M.D., Augusta, Ga., to Miss Martha Miller, of Macon, Ga., October 26.

WILLIAM B. SHICK, M.D., to Miss Mable D. Tully, both of Philadelphia, September 21.

GEORGE CONNOR TRAWICK, M.D., to Miss Alice Rodes, both of Nashville, Tenn., October 10.

THOMAS W. PENROSE, M.D., to Miss Esther M. Eastburn, both of Philadelphia, October 9.

RAY RHINALDO HARRIS, M.D., Dubuque, Iowa, to Miss Ethel Alice Larkin, of Chicago, October 20.

AL. EDGAR BILLINGS, M.D., Topeka, Kan., to Miss Clara A. Jaeger, of Rich Hill, Mo., September 29.

FLETCHER J. WRIGHT, M.D., Fork Union, Va., to Miss Anne Davis Seay, at Blackstone, Va., October 14.

A. GAZAB, M.D., Cairo, Egypt, to NELLIE CHRISTINE HAMEISTER, M.D., of Kirkwood, Mo., October 25.

SMITH HAMILL HORNE, M.D., Philadelphia, Pa., to Mrs. Caroline S. Reed, of Wayne, Pa., October 14.

WILLIAM MELVIN RUCKLE, M.D., Grand Rapids, Wis., to Miss Olive Bemis, of Neenah, Wis., October 12.

ROY ERNEST SEITZ, M.D., Musselshell, Mont., to Miss Rosa Waters Ridgely, of Washington, D. C., October 7.

ARCHIBALD EASTWOOD CHACE, M.D., Tarrytown, N. Y., to Miss Ruth Lombard, of Nyack, N. Y., October 16.

LEO L. C. LEMOINE, M.D., St. Louis, Mo., to Miss Kate Zimmer, of Waterloo, Ill., at Clayton, Mo., October 3.

W. L. DUBOIS, M.D., Towner, N. D., to Miss Mayme L. Dougherty, of Rockwell City, Iowa, September 30.

CHARLES WALLACE EDMUNDS, M.D., Ann Arbor, Mich., to Miss Lillian Virginia Kaminski, of Richmond, Ind., September 15.

Deaths

Randal R. Hunter, M.D. Jefferson Medical College, Philadelphia, 1876; of Fulton, Kan.; a member of the American Medical Association; gold medalist of the Howard Association of Memphis, Tenn., 1878; a member of the Association of Military Surgeons of the United States; acting assistant surgeon U. S. Army, and major and brigade surgeon U. S. V., during the Spanish-American War, with service in Cuba; city chemist and a member of the Board of Health of Kansas City, Mo., from 1887 to 1894; emeritus professor of chemistry in the University Medical College of Kansas City; died in Hot Springs, Ark., October 13, from paralysis, aged 54.

Lewis Albert McFadden, M.D. Kentucky School of Medicine, Louisville. 1881; a member of the American Medical Association, and vice-president of the Peoria (Ill.) Medical Society; a member of the staff of St. Francis Hospital, Peoria; formerly physician of Peoria county and a member of the city board of health; chairman of the local board of U. S. pension examining surgeons; in 1896 elected alderman, and in 1901, appointed health commissioner; in 1886, alderman of Aurora, Texas, and afterward postmaster of Virginia, Mo.; died at his home October 16, from cancer of the intestine, aged 61.

Leonard Pearson, B.S.; V.M.D.; M.D. (Hon.) University of Pennsylvania, Philadelphia, 1907; of Philadelphia; dean of the Department of Veterinary Medicine in his alma mater; formerly state veterinarian of Pennsylvania; and a member of the Pennsylvania Live Stock Sanitary Board; a member of the department of the health of the State of Pennsylvania and the board of health of Philadelphia; one of the foremost exponents of preventive veterinary medicine; died suddenly in Spruce Creek, New Foundland, September 20, aged 41.

William Hudson Pitt, M.D. University of Buffalo, N. Y., 1879; for eighteen years professor of physics in the Buffalo High School; in 1881 and 1882, state analyst of foods and drugs; and in 1884 appointed professor of chemistry and physics in Niagara University; a biologist and chemist occupying a commanding position among the scientists of the country; died at his home in Friendship, N. Y., July 11, aged 78.

William A. Gordon, M.D. Rush Medical College, Chicago, 1869; of Winnebago, Wis.; a member of the State Medical Society of Wisconsin; a veteran of the Civil War; for fifteen years superintendent of the Northern Hospital for the Insane, Oshkosh; an eminent phys[illegible] alienist, and brilliant scholar; died in t[illegible] October 12, from hemorrhage, due to a [illegible]lder, aged 62.

James L. Mounts, M.D. Starling Medical College, Columbus, Ohio, 1856; a member of the American Medical Association; surgeon of the Thirty-first and One Hundred and Forty-fourth Ohio Volunteer Infantry during the Civil War; state senator in 1879; surgeon to the Panhandle and Columbus and Hocking Valley railroads; died at his home in Morrow, Ohio, October 21, aged 78.

Joseph Lewis Snively, M.D. Jefferson Medical College, Philadelphia, 1877; a member of the American Medical Association and Cumberland Valley Medical Association; president of the Medical Society of Franklin County, Pa., in 1901; and afterward district censor for Franklin county; died at his home in Shady Grove, Pa., October 14, from typhoid fever, aged 58.

George Clark McNett, M.D. New York University, New York City, 1881; a member of the American Medical Association; local surgeon for the Delaware, Lackawanna and Western Railroad; for several years chief surgeon of the State Soldiers' Home, Bath, N. Y.; died in that place, October 15, from disease of the kidney, aged 52.

Lafayette Shoemaker, M.D. Kentucky School of Medicine, Louisville, 1893; a Confederate veteran; a member of the State Medical Association of Texas; and formerly vice-president of [illegible] Choctaw County (Ala.) Medical Society.; a practitioner [illegible] more than thirty-five years; died at his home in Axtell, [illegible]ptember 23, aged 68.

Lewis Henry Bodman, M.D. College of Physicians and Surgeons, New York City, 1863; a member of the American Medical Association; consulting physician to St. Vincent's and the Toledo Hospital, Toledo, Ohio; a medical cadet in the Federal service during the Civil War; died at his home, October 18, aged 69.

Alexander Macnab, M.D. University of Aberdeen, Scotland, 1861; a member of the Iowa State Medical Society; assistant surgeon of the Twelfth Missouri Volunteer Infantry during the Civil War; died at the home of his son in Rock Rapids, Iowa, July 28, from cerebral hemorrhage, aged 74.

Maurice John Stack, M.D. University of Georgetown, Washington, D. C., 1876; for thirty-three years assistant superintendent of St. Elizabeth's Hospital, the Government Hospital for the Insane, Washington; died in that institution, October 17, from cancer of the throat, aged 55.

Thomas Keefe, M.D. Cooper Medical College, San Francisco, 1882; for many years a practitioner of Snohomish, Wash.; and a member of the Snohomish County Medical Society; died suddenly at his home in Georgetown, Wash., January 3, from heart disease, aged 71.

Henrietta Payne Westbrook, M.D. Woman's Medical College of Pennsylvania, 1880; of Philadelphia; president of the Health Protective Society and the Woman's Press Club of Philadelphia; died at her summer home in Burrillville, R. I., October 16, aged 74.

Rebecca Cooper Hallowell, M.D. Woman's Medical College of Pennsylvania, Philadelphia, 1878; formerly a medical missionary to the Indians in Southern California; died at her home in Haddonfield, N. J., October 12, from heart disease, aged 77.

Josiah M. Thompson, M.D. Jefferson Medical College, Philadelphia, 1875;; a veteran of the Civil War; and once president of the federal board of pensions of Kansas; died at his home in Kansas City, Kan., October 11, from bronchitis, aged 66.

Nova William Wingo, M.D. University Medical College of Kansas City, Mo., 1892; formerly of Harris, Mo.; died in his office in Chillicothe, Mo., October 11, from the effects of carbolic acid, self-administered, it is believed with suicidal intent, aged 45.

Ralph A. Polly, M.D. Memphis (Tenn.) Hospital Medical College, 1902; of Rogers, Texas; a member of the State Medical Association of Texas; died in a hospital in Temple, Texas, August 21, after an operation for the removal of gall-stone, aged 36.

John Williams (license, Ind., 1897); for more than sixty-five years an Eclectic practitioner of Clay county, Ind.; a veteran of the Civil War; died at the home of his daughter, near Bowling Green, October 4, from senile debility, aged 97.

William Joseph Dodd, M.D. Bellevue Hospital Medical College, New York City, 1865; surgeon on the U. S. Army Hospital Steamer *Deford*, during the Civil War; died at his home in Jersey City, N. J., October 20, from senile debility, aged 79.

Edmund B. Mosher, M.D. Louisville (Ky.) Medical College, 1871; surgeon of the One Hundred and Seventy-Second Ohio Volunteer Infantry during the Civil War; died at his home in Columbus, Ohio, October 11, from disease of the liver, aged 71.

Solomon Apfel, M.D. University of Lemberg, Austria, 1871; once a member of the Austrian Chamber of Deputies; and mayor of Kolboszzawa, Austria; died at his home in Brooklyn, N. Y., October 16, from paralysis, aged 65.

Milton Homer Collins, M.D. University of Tennessee, Nashville, 1884; a member of the Medical Society of the State of Alabama; died at his home in North Birmingham, October 16, from cerebral hemorrhage, aged 51.

Hammond Hampton Garner, M.D. University of Maryland, Baltimore, 1902; of Lake Toxaway, N. C.; surgeon of the steamer *Dextero*; died in the City Hospital, Santos, Brazil, South America, in July, aged 31.

William Levi Fleming, M.D. Missouri Medical College, St. Louis, 1868; a member of the Shelby County (Ill.) Medical Society; died at his home in Shelbyville, October 10, from disease of the lungs, aged 74.

Abram Canfield (license, Minn., exemption certificate, 1883); for forty-three years a practitioner of Sauk Center, Minn.; died at the home of his son in that city, October 7, from senile debility, aged 87.

Joseph Saunders, M.D. Indiana Medical College, Indianapolis, 1874; for twenty years president of the Madison County, Ind., Farmers' Insurance Company; died at his home near Anderson, recently, aged 60.

James McGuire, M.D. New York University, New York City, 1857; formerly a member of the Medical Society of the State of North Carolina; died at his home in Mocksville, August 21, aged 80.

Frederick B. Williamson, M.D. Starling Medical College, Columbus, Ohio, 1888; a member of the Ohio State Medical Association; died at his home in Massillon, October 14, from pneumonia, aged 44.

Frank R. Calhoun, M.D. Medical College of the State of South Carolina, Charleston, 1867; for four years a surgeon in the Confederate service; died at his home in Cartersville, Ga., October 15, aged 74.

Alfred Swift Houghton, M.D. College of Physicians and Surgeons, New York City, 1880; for several years connected with the New York civil service; died at his home in St. Albans, Vt., July 29.

Charles Willard Pierce, M.D. Harvard Medical School, Boston, 1900; a member of the American Medical Association; died at his home in Allston, Boston, October 9, from typhoid fever, aged 37.

William Newton Rand, M.D. University of Vermont, Burlington, 1883; examiner in lunacy; died at his home in Binghamton, N. Y., September 25, from cerebral hemorrhage, aged 50.

Roger Button Smith, M.D. Hospital College of Medicine, Louisville, 1897; of Orchardville, Ill.; is said to have committed suicide, by gunshot wound, at his home, October 16, on account of domestic troubles, aged 37.

Jacob Goldstein, M.D. Bellevue Hospital Medical College, 1895; of New York City; died in Mount Sinai Hospital, October 13, from acute yellow atrophy of the liver.

Joseph W. Davenport., M.D. Medical College of the State of South Carolina, Charleston, 1848; of Tyler, Texas; died at the home of his daughter in that place, October 14, aged 84.

John W. Alford, M.D. Eclectic Medical Institute, Cincinnati, 1875; a veteran of the Civil War; of Mullinville, Kan.; died in a hospital in Hutchinson, Kan., October 11, aged 67.

George T. Snode, M.D. Starling Medical College, Columbus, Ohio, 1888; a member of the Ohio State Medical Association; died at his home in Sarahsville, October 13, aged 51.

Villanovia Mason Burdick, M.D. University of Vermont, Burlington, 1887; died at his home in Dexter, Maine, August 23, from cancer of the stomach, aged 57.

Oliver Henry Reiley, M.D. St. Louis University, School of Medicine, 1906; died at his home in Red Oak, Iowa, September 12, from acute gastritis, aged 27.

James B. Statler (years of practice, Pa.); for thirty-five years a practitioner of New Paris, Pa.; died at his home, September 27, from dysentery, aged 65.

William H. Mann, M.D. Atlanta (Ga.) Medical College, 1892; of Glennville, Ga.; died in Savannah, October 17, from septicemia, due to a carbuncle, aged 43.

William Ramsey, (license, years of practice, Ohio); for fifty-seven years a practitioner of Delta; died at his home in that place, October 10, aged 82.

M. H. Christian (license, Ill.); for many years a practitioner of Camargo, Ill.; died at his home in Summit township, near Effingham, October 8.

Abram Duane Salisbury, M.D. University of Michigan, Ann Arbor, 1865; died at his home in Midland, Mich., October 16, from septicemia.

Oswald Edward Jacob Kauffman, M.D. Tulane University, New Orleans, La., 1905; died at his home in Plaisance, La., October 8, aged 26.

David Hamilton, M.D. Queen's University, Kingston, Ont., 1862; of Batavia, N. Y.; died in the Batavia Hospital, October 8, aged 70.

William Rhea Douthit, M.D. Vanderbilt University, Nashville, 1892; died at his home in Louisville, Tenn., October 16, aged 48.

Harry B. Pleasants, M.D. Medical College of Virginia, Richmond, 1879; died at his home in Hollins, Va., October 15, aged 54.

Barbara Albrecht, (license, Ohio, ten years practice, 1896); died at her home in Cincinnati, March 28, from diabetes, aged 74.

Sara Jane Williams (license, Mass., 1894); died in Boston, Mass., Sept. 27, 1908, from general paresis, aged 67.

W. J. Trent, (license, N. C.); died at his home near Earl, August 1, aged 76.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION

Thirty-Fifth Annual Meeting, Held at St. Louis, Oct. 12-14, 1909

(Continued from page 1419)

Tuberculous Toxemia in Surgery

DR. ALEXANDER C. WIENER, Chicago: In this paper I present the following therapeutic conclusions: 1. Obstruction of the respiratory organs which curtail the intake of air are to be removed by the nose and throat surgeon. Too much stress cannot be laid on the removal of enlarged tonsils and adenoids by the skilled operator. Other anomalies, such as phimosis, should be remedied. 2. Mechanical treatment should be undertaken to correct all deformities of the skeleton, particularly the spine and chest. Children and adults who begin to develop round shoulders, with the subsequent hollows below and above the clavicles, need urgent treatment. It is harmful to advise the wearing of apparatus for support during the growing period. Braces should be discarded as therapeutic agents in the treatment of deformities of the spine due to rickets. Instead, the treatment should consist of: (a) Complete mobilization of all the intervertebral and vertebro-costal joints. (b) Correction of deformities of the vertebra and ribs. (c) Active and passive exercise of the respiratory muscles, including the diaphragm.

DISCUSSION

DR. F. M. POTTENGER, Monrovia, Cal.: The more we study the infection in tuberculosis the more we come to the conclusion that infection takes place in a great number of people early in life, and that most of us go through life with at least quiescent foci of tuberculosis within our bodies. These quiescent foci are not always negative and they do produce symptoms which have not been generally recognized. Toxemia in young neurasthenic school girls in my opinion is undoubtedly due to latent foci of tuberculosis and I have seen a number of such patients recover after treatment for tuberculosis.

Elements of Success in Surgical Work

DR. A. H. CORDIER, Kansas City, Mo.: 1. The field of surgery is a vast one and is best covered by the specialist in some of its departments, the eye and the ear especially. 2. Surgery and medicine should go hand in hand in the treatment of border-line cases, but should be divorced in the strictly surgical or strictly medical cases. 3. The selection of a surgeon for a given case should be from no other standpoint than that of his recognized ability. 4. A surgical operation should be performed as quickly as possible, consistent with good and completed technic. 5. All unnecessary and rough handling of important tissues and organs should be avoided. 6. Careful short anesthesia will help to keep the death-rate low. 7. Careful hemostasis with proper ligature material is an important element in successful surgery. 8. Thorough aseptic technic should be carried out and may be obtained either with or without rubber gloves and mask. 9. Lawn-tennis suits and gloves are only too often the avenues leading to wound infection. 10. Short postgraduate courses instill false surgical confidence and lead to many surgical disasters. 11. Honesty and sincerity should ever be the keynote in deciding as to the advisability of performing any surgical operation. 12. Mental tranquillity of the patient is of much importance preceding the performance of some surgical operations.

DISCUSSION

DR. H. HENRY CARSTENS, Detroit: No one has a right to practice surgery, and especially abdominal surgery, unless he has been an assistant for at least one year with some first-class surgeon, in a hospital where he has seen hundreds of operations and has witnessed the troubles, trials and complications that are encountered. Educated people know and find out who are the good surgeons. The general practitioner ought to know who is a good surgeon and ought not to trust everyone to perform operations which are attended with great danger to life.

DR. M. C. MCGANNON, Nashville: I am not willing to admit that surgical work of the pioneer was as good as that which is being done to-day. The enthusiasm of youth leads many a recent graduate to rush into the field of large surgery where he had better keep out until better trained. But how are we to stop that? It is the duty of this and other societies to adopt such measures as will prevent enthusiastic young men from rushing into a field of work that they cannot fill. Many of us have seen disasters following the surgical work of inexperienced men.

DR. CHANNING W. BARRETT, Chicago: Surgery has come to occupy a large place in the world, and it is our business as members of the medical profession to see that our surgical work is made just as successful as possible. The time has gone by when a man can plunge into surgical work and kill patients in order to learn how to do surgery. The opportunities for learning surgery now are too great and too cheap to permit of inexperienced men operating, and surgeons are only too willing to train those who wish to become surgeons.

Conditions Simulating Surgical Diseases

DR. M. C. MCGANNON, Nashville: It is not often that a surgeon is called on to reverse a diagnosis of chronic peritonitis in favor of spinal neurosis of traumatic origin, and yet such was my experience a few months ago. Cases of appendicitis have been on many occasions confounded with pleurisy and pneumonia. Many authors have called attention to the fact that pain associated with pneumonia and pleurisy, especially in children, may, if referred to the abdomen, and, if right-sided, occasion a diagnosis of appendicitis. Two such cases have been referred to me for operation, in which appendicitis was so closely simulated as to deceive good practitioners.

DISCUSSION

DR. EDWIN WALKER, Evansville: I am reminded of a case in which a man had locomotor ataxia, and the proposition was made to operate on him for gall-stones. The patient afterward fell into the hands of a surgeon who operated for gall-stones, but no stones were found. This man subsequently died of acute pneumonia and from an extension of the ataxia.

Dr. J. Henry Carstens, Detroit: Two years ago a woman was brought to me with large fibroid tumors. She had been vomiting for three weeks off and on and could not sleep. I ran my finger over the clavicle and over the tibiæ, gave her one-quarter of a grain of bichlorid of mercury hypodermically every day, and in four or five days she was able to sleep well, the vomiting ceased and the fibroids had nothing to do with those symptoms. I saw a man who was supposed to have had gall-stones. I looked at his tongue, saw a blue line along the edge of it, and said to him: "You are a painter, are you not?" And he replied, "Yes, sir." I told him he was not suffering from gall-stones, but from lead poisoning.

Dr. J. R. Eastman, Indianapolis: The general practitioner and internal medicine man ought to be educated along these lines. I went with two competent physicians in the summer in the country to examine a little girl whose case was diagnosticated as appendicitis. A mass had been described as present in the right groin. The little girl was 11 years of age, and these physicians considered it a clear case of appendicitis. While I sat at the bedside she took her handkerchief, expectorated profusely, and it proved to be tuberculosis.

Dr. Richard A. Barr, Nashville: I was called to the country a year ago to operate for appendicitis, the operation having been delayed for a number of days. On examination, I decided that this patient did not have appendicitis, but typhoid, and was able to persuade the attending physician that *I was correct, and no operation was done. I took some of* the patient's blood with me, had it examined; a Widal reaction was made, which proved to be negative.

Dr. William B. Burns, Memphis: I have seen some cases presenting symptoms of appendicitis which were as positive as we usually see them, but examination of the blood showed the presence of malarial parasites and hypodermic injections of quinin in four hours removed all the symptoms.

Various Operative Technics for Dislocated Kidney and Indications for Their Application

Dr. E. Harlan, Cincinnati, reviewed the work and opinions of various surgeons on dislocated kidney and said that operative cases of dislocated kidney may be summed up as follows:

1. Cases presenting periodical crises: (a) chronic recurent headaches and other nervous surcharges; (b) gastrointestinal; (c) renal; (d) hepatic; (e) appendiceal; (f) various bladder and pelvic symptoms.
2. Pathologic kidney: (a) albuminuria (postural); (b) hydronephrosis (recurrent).
3. Insanity (Suckling).
4. Persistent lumbar dragging or colonic backache which is unrelieved by medicinal treatment or by the use of an abdominal elastic.
5. Dependent pathology: (a) appendiceal irritation, congestion or inflammation; (b) stricture or partial occlusion of the bowel or bile tract; (c) adhesions, (e) ptosis or ulcer of the stomach.

He tabulated the operative steps and measures which have been employed in fixation of the kidney from the time of the first operation by Dowell, of Galveston, Texas, in 1874, to the present, including a description of the technic as used by the most prominent authorities in this work at the present time, with a discussion of the merits of the several methods and their application. He ascribed the operation of posterior nephropexy to Hahn and presented the evolution of its many modifications with the probable cause or suggestion which give rise to each. Lateral nephropexy he said belongs to M. L. Harris of Chicago. He described anterior nephropexy as first exploited by himself as well as the modification of the latter by Bishop, of Manchester, England. He also gave a summary of the methods of operating for dislocated kidney.

He predicted that in the near future all posterior operative procedures and all operations intended to "fix" the kidney would become obsolete, and only those methods applied which relieve and replace an obstructed ureter, eliminate the pocket and support the kidney at its lower pole while making sufficient correction of a disabled peritoneum to prevent either the upper or lower pole of the kidney from protruding into the peritoneum or bowel.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA

Fifty-Ninth Annual Session, held in Philadelphia, Sept. 27-30, 1909

(Continued from page 1425)

SYMPOSIUM ON PULMONARY TUBERCULOSIS

The Early Diagnosis of Pulmonary Tuberculosis

Dr. Charles H. Miner, Wilkes-Barre, Pa.: Of 272 members of 157 families of tuberculous patients attending the state tuberculosis dispensary No. 1, in Wilkes-Barre, 180 or 66 per cent. were found to be tuberculous. Of those examined for signs of obstructed respiration, 50 cases of adenoids and enlarged tonsils were found, and 35 of these patients have been operated on at the dispensary. To diagnose tuberculosis in its real incipience we must look for it during infancy and childhood, localized in the lungs and bronchial glands. The time for making an early diagnosis in adults is when renewed activity first takes place or there has been a reinfection from without.

The Roentgen-Ray Diagnosis of Pulmonary Tuberculosis

Dr. Charles Lester Leonard, Philadelphia: This method of diagnosis is of distinct value in adding to and confirming the findings made by other methods of physical diagnosis and in obtaining mechanically a permanent record of the condition present. To obtain the necessary detail and to eliminate motion in the lungs, due to respiratory movements and the heart's pulsation, exposures of one-quarter of a second are essential. The method is valubale in the early stages of pulmonary tuberculosis in adding data by which the diagnosis is rendered certain. Localized empyemata can be differentiated from dilated and occluded bronchi and pyothorax and pneumothorax of slight extent can be found, while periodical thickenings and effusions, whether of tuberculous or other origin, are clearly seen. The relative height of the diaphragm is an unreliable index of the capacity of the lungs, since variations in the positions of the mediastinal viscera affect their relative capacity. This method has also shown that calcification of the sternocostal cartilages is a comparatively frequent accompaniment of pulmonary tuberculosis and may involve all the cartilages.

Tuberculosis of the Lungs Without Cough or Expectoration

Dr. Joseph P. Walsh, Philadelphia: The paper is a report of 13 new cases and 442 cases from the literature of tuberculosis of the lungs without cough or expectoration, and general statistics on the frequency of this occurrence. Since tuberculosis of the lungs can be readily diagnosed, according to German and American statistics in at least 5 per cent. of cases before cough and expectoration begin, it is important not only not to wait for the discovery of tubercle bacilli in the expectoration, but also not even for cough or the expectoration itself.

The General Practitioner and the Incipient Case of Pulmonary Tuberculosis

Dr. Arthur A. Watkins, St. Benedict: A distressingly large number of physicians either hesitate to make a diagnosis of an early case or are unable to recognize it. In rural districts the number of tuberculous patients receiving modern treatment is incredibly small. The average family physician does not make a diagnosis until the physical signs are well advanced (Trudeau). Thus in incipient cases the patients are neglected and inadvertently imposed on. It is probable that the average family physician has from 25 to 100 cases of pulmonary tuberculosis among his patients.

The Prognosis in Advanced Pulmonary Tuberculosis

Dr. William B. Stanton, Philadelphia: The majority of patients who apply for treatment to the general practitioner are in advanced stages. Believing that good results are obtained only in incipient cases, the treatment is not pursued with the optimism and enthusiasm that should characterize it. Large left-sided lesions often admit of a guardedly favorable prognosis, while large right-sided lesions do not.

Discussion on Pulmonary Tuberculosis

Dr. Edgar M. Green, Easton: I believe that the fault in diagnosticating tuberculosis lies not so much in the lack of ability as in the lack of thorough examination. One thing of considerable help in the diagnosis of early cases is the knowledge that at times the bacilli are present in the urine when there is no expectoration. In one case there was occasional rise of temperature and a careful examination showed a very small focus in the upper portion of the left lung. There was absolutely no cough and there was no other symptom. I believe these cases in which there is no cough are much more frequent than we think.

Dr. Arthur A. Watkins, St. Benedict: I do not agree with Dr. Green that the fault is due to negligence of the profession. In a recent tuberculosis exhibit in our town, of eleven patients with tuberculosis the physicians who were present would admit that only one had the disease, and in this one the condition was far advanced and a cavity was present.

SYMPOSIUM ON THE CIRCULATION

Importance of Considering the Arterial and Venous Systems in Cardiac Diseases

Dr. Hobart Amory Hare, Philadelphia: Changes in the blood-vessels can be roughly divided for clinical purposes into three great classes, namely, far advanced atheromatous change with calcareous deposits and associated destructive disease of the intima; fibroid change in which the most important lesion is an arteriocapillary fibrosis; vascular spasm whereby the elasticity of the vascular walls is impaired almost as much as when an actual organic lesion is present. While I am aware of the fact that the morbid anatomist may criticise this classification, I hold the opinion that the class of cases characterized by calcareous change with breaking down of the intima is quite a different type of disease from that characterized primarily by spasm and later by spasm and arteriocapillary fibrosis. It is exceedingly rare, in my experience, to meet with marked calcareous change or brittleness in the arterial system of the well-to-do or upper class, and comparatively rare to find high tension due to spasm and fibrosis in the working classes. Hard manual labor does not cause the same arterial changes that are caused by hard mental labor and nervous stress. This is all the more interesting because of the abuse alcohol and syphilitic infection, the two great causes of arterial disease, may be considered to exert an equal or nearly equal influence in both classes. The deduction from these facts, so far as treatment is concerned, is that when calcareous change is well developed little can be done for the relief of the patient; whereas, in the latter type, a good deal can be done, the degree of good depending, of course, on the severity of the lesions in each instance. The recognition of the underlying vascular state, altered by actual illness, is of the utmost importance in prognosis, and of even greater value from the standpoint of therapeutics. Nor is it safe to be content with the examination of one vessel in determining the general arterial state. Aside from the chronic and persistent manifestations the importance of studying vascular changes in acute illnesses is of overwhelming importance. How futile it is to stimulate a heart which is pumping against a high pressure in narrowed and tortuous vessels unless we simultaneously relieve it of some of its labor by reducing that pressure by the nitrites. To give digitalis under these circumstances, in the face of high tension, is equivalent to giving a horse an extra meal and then doubling his load.

Blood-Pressure Past Middle Life in Diagnosis, Prognosis and Treatment

Dr. Joseph H. Barach, Pittsburg: This paper is based on blood-pressure studies with the Erlanger sphygmomanometer, in a series of over seventy males, and includes observations and deductions as to the value of the study of the blood-pressure past middle life in diagnosis, prognosis and treatment. A chart of blood-pressure readings in normal individuals from the age of 10 to 90 years showed that with the advance of life the blood-pressure seems to rise steadily. At the age of 40 the blood-pressure was 115, at 60 it was 135 and at 80 it was 150. With these figures as a medium normal, 20 mm. above or below represents the limit of the normal range under any circumstances; figures beyond that were always associated with something pathological. In treatment the greatest effect comes with the regulating of the patient's mode of living. As accessory measures the various depressor drugs are to be used cautiously.

Analysis of Sixty-two Cases Exhibiting the Xiphisternal Crunching Sound

Dr. Myer Solis Cohen, Philadelphia: An analysis of 62 cases is presented showing this sound, which I described in 1903. While usually heard over the ensiform cartilage and the lower end of the gladiolus, the limits at which the sound was sometimes heard was the third rib, above the anterior axillary line and one and a half inches to the right of the sternum. The sound usually was increased when the patient leaned forward and diminished when he lay. In some cases it was loudest during inspiration; in others at the end of this act; in still others at the end of expiration. In many instances it was not affected by the breathing. The great majority of the cases were males, white, and between the ages of 20 and 70. All occupations were represented. In absence of autopsies, the nature of the sound is a matter merely of speculation. Apparently it has little significance. It is consequently important not to mistake the sound for a murmur or a pericardial friction.

Discussion on Circulatory Diseases

Dr. James M. Anders, Philadelphia: In these cases it is important to detect the degree of loss of elasticity of the arterial walls, the degree of sclerosis, and to carefully differentiate that for the sake of treatment from rise of blood-pressure. It is also important to estimate the loss of vasomotor tonus of the arterial walls. These arterial changes are commonly associated with cardiac affections, and it must be remembered that they may predominate in certain portions of the body. The indications for treatment must necessarily vary according to the particular changes. The great difficulty I find is that students and physicians are apt to overlook the fact that these changes are not necessarily disseminated throughout the body, but confined principally to certain portions of the economy. It is also important to detect the lack of elasticity in the veins and the degree of vasomotor tonus of the venous walls. As in the case of the arteries, so with the veins the impediment to the centripetal flow of the blood may be general, or it may be localized to certain portions of the body. The aspirating forces within the thorax must be carefully estimated in the given case. I refer especially to the inspiratory effort in breathing. I agree with Dr. Barach that a rise of blood-pressure is important for diagnosis and that it enables us to make a better prognosis. In arterial sclerosis affecting principally the smaller arteries a rise of blood-pressure is a most important early symptom.

Dr. Edgar M. Green: Dr. Hare spoke of the large element of nervousness in many of the cases of arteriosclerosis. I have been surprised to find that it might be said to be a temperamental condition. I have found that patients who do not relax are more subject to this disease than others. I have seen more patients with arteriosclerosis who did not have syphilis, or who were not alcoholics, than those with these conditions, and yet in almost all this certain neurotic condition was present in a marked degree.

Dr. H. A. Hare: We must recognize that the term sclerosis is rather objectionable to modern pathologists; it is not sufficiently definite. It is true that in a large number of cases there is sclerosis in the sense that there is thickening of the vessels, either because of fibroid change or calcareous deposit. It is also true that in a large number of cases it is not so much actual fibrosis or sclerosis or atheromatous change as it is spasm. It is important to recognize the degree of spasm because in direct proportion to its recognition can we employ therapeutic measures with success and in direct proportion to the degree of sclerosis or actual fibrosis or atheroma can we employ remedies with failure. If there is one important point which we have learned from our studies of pathology in recent years it is that there is a limit to therapeutic usefulness.

MASSACHUSETTS: State House, Boston, November 9-11. Sec., Dr. E. B. Harvey, Room 159, State House.

NEBRASKA: Senate Chamber, State House, Lincoln, November 10-11. Sec., Dr. E. Arthur Carr, 141 South Twelfth St.

NEVADA: Carson City, November 1. Sec., Dr. S. L. Lee.

TEXAS: Levy Bldg., Greenville, November 9-11. Sec., Dr. M. E. Daniel, Honey Grove.

WEST VIRGINIA: Chancellor Hotel, Parkersburg, November 9-11. Sec., Dr. H. A. Barbee, Point Pleasant.

Texas Reciprocity Report

Dr. M. E. Daniel, secretary of the Texas State Board of Medical Examiners, sends us a report of those licensed by that board through reciprocity since Jan. 1, 1909. The following colleges were represented:

LICENSED THROUGH RECIPROCITY

College	Year. Grad.	Reciprocity with
University of Southern California	(1908)	Illinois
Chicago Homeopathic Medical College	(1898)	Illinois
Illinois Medical College..(1901) Indiana, (1903)	(1907)	Illinois
Chicago College of Medicine and Surgery	(1908)	Illinois
American College of Medicine and Surgery*	(1905)	Illinois
Northwestern University Med. School, (1904)	(2, 1908)	Illinois
College of Physicians and Surgeons, Chicago .....(1897) West Virginia; (1903) (2, 1902)	(1907)	Illinois
Rush Medical College......(1881) Minnesota;	(1906)	Illinois
Medical College of Indiana	(——)**	Illinois
University of Iowa, College of Medicine	(1902)	Iowa
Keokuk Medical College, College of Physicians and Surgeons........(1901) (1902) Illinois;	(1905)	Indiana
Physio-Medical College of Indiana	(1890)	Michigan
Kentucky School of Med...(1896) W. Virginia;	(1908)	Kentucky
University of Louisville..(1889) Kentucky; ....(1908)	(1893)	W. Virginia
Hosp. Coll. of Med., Louisville..(1897) Illinois;	(1904)	Kentucky
Baltimore Medical College..(1897) W. Virginia;	(1903)	Maryland
Johns Hopkins University	(1898)	Missouri
University of Maryland	(1906)	Maryland
College of Physicians and Surgeons, Baltimore ....(1893) Virginia;	(1901)	New Jersey
University of Michigan	(1903)	Indiana
University of Minnesota	(1899)	Minnesota
Barnes Medical College..(1898) (1904) (1905)	(1907)	Missouri
Homeopathic Med. College of Missouri..(1883)	(1907)	Missouri
University of Missouri	(1908)	Missouri
St. Louis College of Physicians and Surgeons	(1897)	Missouri
American Medical College, St. Louis	(1907)	Missouri
Kansas City Medical College	(1899)	Missouri
Eclectic Medical College of New York	(1900)	New Jersey
University of Nebraska	(1903)	Nebraska
Omaha Medical College	(1902)	Nebraska
Dartmouth Medical School	(1900)	New Hamp.
Eclectic Medical Institute, Cincinnati	(1906)	Ohio
Medical College of Ohio	(1885)	Nebraska
University of Pennsylvania.(1899) W. Virginia;	(1908)	Maryland
Jefferson Medical College	(1907)	Maryland
Meharry Medical College	(1890)	Illinois
University of Tennessee	(1901)	Missouri
University of the South	(1905)	Maine
Vanderbilt University	(1900)	Missouri
University of Virginia	(1899)	Dist. Colum.
Milwaukee Medical College	(1905)	Wisconsin
University of Palermo, Italy	(1886)	Illinois

* Name changed to Chicago College of Medicine and Surgery in 1907.

** Year of graduation not given.

Nebraska August Report

Dr. E. Arthur Carr, secretary of the Nebraska State Board of Health, reports the written examination held at Lincoln, Aug. 10-11, 1909. The number of subjects examined in was 8; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 7, of whom 6 passed and 1 failed. The following colleges were represented:

College	Year Grad.	Per Cent.
PASSED		
Northwestern Univ. Medical School..(1875) 75;	(1909)	92
University of Maryland	(1909)	87.1
Woman's Medical College of Pennsylvania	(1908)	84.7
Jefferson Medical College..........(1906) 79.5;	(1909)	80
FAILED		
Barnes Medical College	(1909)	68.1

Missouri May and June Reports

Dr. J. A. B. Adcock, secretary of the Missouri State Board of Health, reports the written examinations held at Kansas City, May 17-19, and at St. Louis, June 7-9, 1909. The number of subjects examined in was 12; total number of questions asked, 90; percentage required to pass, 75.

At the examination held at Kansas City, May 17-19, the total number of candidates examined was 78, of whom 51 passed and 27 failed. The following colleges were represented:

College	Year Grad.	Total No. Exam'd.
PASSED		
Northwestern University Medical School	(1903)	1
College of Physicians and Surgeons, Chicago	(1908)	1
Drake University	(1889)	1
University of Kansas..............(1908)	(6, 1909)	7
University of Michigan	(1907)	1
University of Missouri	(1909)	2
St. Louis University	(1906)	1
Ensworth Medical College	(1909)	6
Univ. Med. Coll., Kansas City....(2, 1908)	(17, 1909)	19
Barnes Medical College	(1909)	4
Washington University	(1908)	1
St. Louis College of Physicians and Surgeons	(1909)	3
Creighton Medical College	(1908)	1
Jefferson Medical College	(1908)	1
Vanderbilt University	(1909)	1
Meharry Medical College	(1909)	1
FAILED		
University of Kansas..............(1906)	(1908)	2
Maryland Medical College	(1902)	1
Detroit College of Medicine	(1908)	1
St. Louis College of P. & S.....(1901) (1908)	(1909)	3
University Med. Coll. Kansas City..(3, 1908)	(9, 1909)	12
Ensworth Medical College...........(1908)	(2, 1909)	3
Barnes Medical College	(1909)	1
Meharry Medical College.....(1907) (2, 1908)	(1909)	4

At the examination held at St. Louis, June 7-9, 1909, the total number of candidates examined was 144, of whom 111 passed and 33 failed. The following colleges were represented:

College	Year Grad.	Total No. Exam'd.
PASSED		
Georgia College of Electic Medicine and Surgery	(1904)	1
Rush Medical College..............(1874)	(2, 1908)	3
Tulane University of Louisiana	(1909)	1
St. Louis University........(1905) (1908)	(32, 1909)	34
Washington University, St. Louis....(1908)	(39, 1909)	40
University of Missouri	(1909)	1
Barnes Medical College..............(1908)	(1909)	20
St. Louis College of Physicians and Surgeons	(1909)	7
American Medical College	(1909)	2
Homeopathic Medical College of Missouri	(1909)	1
Missouri Medical College	(1890)	1
FAILED		
Howard University	(1907)	1
St. Louis College of Physicians and Surgeons.. ....(1906) (1907) (2, 1908)	(6, 1909)	10

National Conservation of Health as an Economic Measure.—Professor Irving Fisher, president of the American Health League, arguing for a national department of health, says in the New York *Christian Advocate:* The present interest in school hygiene augurs well for the future interest in and realization of public health. Perhaps an even greater good omen is found in the growing willingness of commercial establishments to conserve the vital machinery entrusted to their care as well as they conserve the machinery of iron and steel. A railway which works its engineers and signal men beyond the fatigue point reaps its just reward in its losses from collision. Incidentally the public loses life and limb. When insurance companies shall have introduced sanatoria, disseminated educational leaflets, and otherwise tried to promote public health from financial motives, we shall, from a practical point of view, have taken the greatest step forward yet achieved.

Medicolegal

Life Tables Cannot Be Used in Estimating Future Suffering—Largest Verdict

The Supreme Court of Iowa says, in the personal injury case of Canfield vs. C. R. I. & P. Railway Co. (121 N. W. R. 186), that counsel stated that plaintiff's expectancy of life was nearly 43 years, and based their argument in support of the verdict rendered in his favor for $49,000 on that proposition. As to the pecuniary injury to his estate by his injury, that was doubtless permissible, but in estimating his future suffering and the expenses he would be to, and all other matters which had to do with prospective damages, it was perfectly manifest that life tables could not be accepted as a basis. The statistics from which these were compiled were not based on the experience of men crippled as the plaintiff was, but on men in health, or, at least, on men who were not injured as the plaintiff was, and they afforded no criterion whatever as to his expectancy of life. If he was injured as badly as his surgeons said he was; was suffering as they claimed; was as nervous as they would have the court believe; had the exposed bone and running sores on his leg; and the liability to infection as they described, he was not likely to live many years. Indeed, his time, if he was injured as claimed, must of necessity be short. Of course, an operation might prolong his life, but if so, he would be relieved of his bodily suffering, although not his mental, due to his deformed condition. The court wishes to point out this fundamental fallacy underlying the argument made by counsel.

Going to the verdict of $49,000, the court says that this was undoubtedly one of the largest ever returned in a personal injury case. Indeed, it is the largest one of which the court has any knowledge, considering the position in life and earning powers of the party injured, who was an unskilled section hand 18 years of age, with an income of $435 a year, when injured. In the accident in which he was injured he was thrown something like 25 feet by a train, and struck on his head. His right knee was mashed, and the bone broken just above the knee. His left hip was broken, and left leg about the middle. His right arm was broken in three places, and the right shoulder hurt. His nose was cut, and there were cuts over the eye, over the eyebrow, and on the chin, and his scalp was torn off. He was entitled to compensation for present, past, and future pain and suffering, and to an amount sufficient to meet his past, present and future expenses caused by the injury. But, as already stated, he was not entitled to compensation for these on the theory that he would live to his full expectancy. This theory was plausibly argued before the court, but such an argument is without foundation, in that it proceeds on an entirely wrong basis. Again, in justification of the verdict, the members of the court of jury were asked to say what amount would induce them to voluntarily put themselves in a position to receive such injuries. Of course, the answer would be: No sum could be named which would be sufficient. This was another fallacy, but one which undoubtedly appealed to the trial jury. Twenty-five thousand dollars is the largest amount that the court would not deem an excessive award in this case.

Summary Power Necessary for Health Officers

The Supreme Court of Wisconsin, in State ex rel. Nowotny vs. City of Milwaukee (121 N. W. R. 658), says that a health officer who is expected to accomplish results must possess large powers and be endowed with the right to take summary action, which at times must trench closely on despotic rule. The public health cannot wait on the slow processes of a legislative body, or the leisurely deliberation of a court. Executive boards or officers, who can deal at once with the emergency under general principles laid down by the lawmaking body, must exist if the public health is to be preserved in cities.

There is nothing of greater importance relating to the food supply of a great city than that the milk sold should be pure and wholesome, and the common council of Milwaukee, realizing this fact, and realizing also that it was imperative that action should be quick and decisive if it is to be efficient, passed ordinances requiring, under penalties, that all milk sold must be unadulterated, must meet certain standards, and be obtained from healthy cows fed on wholesome feed, and further requiring that every milk vendor must obtain a license from the health commissioner, "which license may at any time be revoked by the commissioner of health for violation of the provisions hereof, or for any good or sufficient cause." The court is convinced that the council had power to pass the ordinance and vest the power of issuing and revoking licenses in the health commissioner by virtue of the power to "tax, regulate, and restrain" the "vendors of milk," and to "regulate and restrain the sale of milk," given to it by the city charter.

The requiring of licenses and the reserving of the power to revoke such licenses, in case of misconduct or violation of law, is well recognized as one of the most effective means of regulating and restraining a business that has yet been discovered, but the power of revocation would amount to little if it could not be vested in an executive officer or board with power to act quickly. The sale of infected milk for a single hour might produce an epidemic of typhoid fever which would sweep hundreds to the grave. The importance of reserving in some executive official the power to revoke can hardly be overestimated. Prosecutions to recover fines and penalties may drag their weary lengths along for weeks and months, and even then prove ineffective; but the revocation of the license remedies the evil and avoids the danger of the spreading of disease at once. It is regulation in the most effective sense. The court has no hesitation in holding that, when the city was given the power to license, restrain, and regulate the sale of milk, it also took power to revoke licenses, and that it might vest such power in the health commissioner, with the right to exercise the same summarily and even without notice.

Denial of Physical Examination on Affidavit of Attending Physician

The Supreme Court of Michigan says that the plaintiff in the personal injury case of Logan vs. Agricultural Society of Lenawee County (121 N. W. R. 485) claimed an injury to her spine and sexual organs. A notice was given to take her deposition at her home, on the ground that she was unable to attend the trial. After that notice was served, the defendant filed a petition asking an order that two physicians named be permitted to examine the plaintiff. In reply her physician certified that she was confined to bed as a result of the injury, that she was weak and extremely nervous, and that in his judgment the physical examination prayed for in the petition would be disastrous, and would have a tendency to greatly increase her nervous disorder and prevent her recovery. The trial court filed an opinion denying the application on the strength of the affidavit of her physician. The Supreme Court does not think that in this case the trial court abused its discretion, especially in view of the fact that a physician on behalf of the defendant was present when the plaintiff's deposition was taken, and testified on the trial, and that the defendant's other physician had examined the plaintiff at the time of her injury. All of the circumstances connected with the refusal were in evidence, and the trial court on this point instructed the jury that if they found that the defendant's physicians "were not given a fair and reasonable opportunity, both or one of them, to examine or see the plaintiff, and to make a modest and reasonable investigation for the purpose—and in good faith—of making an examination for the purpose of ascertaining her condition of health and the character and extent of her injuries, if any, then you should take this as against the plaintiff, and have the right to infer that such investigation would not be favorable to her claim in this case. Furthermore, you should consider carefully all the testimony in the case on that subject, and say whether she has refused at all times or not, and whether those refusals have been reasonable or not. And if not, you have a right to consider it as a circumstance against her to that extent; but if her reasons seem to be good and adequate in your judgment for doing as she has done under the circumstances, then, of course, it would not be considered by you as of any force or effect against her. You may consider all the evidence on that subject in determining what the real situation is." The Supreme Court sees no reason to disturb the ruling of the trial court.

Current Medical Literature

Titles marked with an asterisk (*) are abstracted below.

Medical Record, New York

2 Early Diagnosis of Malignant Disease of the Larynx. W. F. Chappell, New York.
3 *Precocious Tertiary Syphilis; Case with Manifold Manifestations. H. F. L. Ziegel, New York.
4 *The Care of the Nursing Breasts—Their Development During Neurasthenic Puberty. G. E. Abbott, Pasadena, Cal.
5 Great Improvement in Advanced Cases of Pulmonary Tuberculosis Under Sanatorium Care. H. Greeley, Brooklyn.
6 Mastoiditis, Complicated by Purulent Leptomeningitis, Epidural Abscess, and Sinus Thrombosis. A. Braun, New York.

1. **Diet in Tuberculosis.**—According to King, the following standards are applicable to ambulant cases of comparatively quiescent tuberculosis under sanatorium treatment:

> 1. For young adult men of the working class on very light exercise from 2800 to 3200 calories, of which from 110 grams to 125 grams shall be protein.
> 2. For the same class on 5 or 6 hours vigorous exercise (sawing or chopping wood, working with shovels, pickaxes, barrows, etc.), from 3100 to 3600 calories, of which 125 grams to 140 grams shall be protein.
> 3. For women of this class 200 calories and approximately 10 grams protein may be deducted in each case.
> 4. Four young adult men, whose occupation has been more sedentary—*e. g.* clerks, bookkeepers, tailors, students, etc., on moderate exercise (walking from one to three hours daily), 2600 to 3000 calories, of which not over 115 grams need be protein.
> 5. For women of this class not to exceed 2500 calories and 100 grams protein.
> 6. For older patients, a slight reduction in calorific value and a considerably lower protein constituent are desirable in each case.
> 7. For the country dweller a somewhat larger bulk without increase in protein value is usually desirable, all other conditions being similar, than is the case with the patient from the city.

Diets constructed on these standards in two divisions of the Loomis Sanatorium during the past year have proved more satisfactory than any which have been previously employed. During the autumn and winter of 1905 and 1906 the standard was protein, 166 grams; fat, 214 grams; carbohydrates, 323 grams; calories, 3955. Patients seemed to do very well on this diet. Weight gains were satisfactory, but digestive disturbances were not uncommon.

3. **Precocious Tertiary Syphilis.**—A patient with syphilis which had not been systematically treated, fifteen months after infection began to exhibit tertiary manifestations which appeared in the following order: (1) Ulcer of the right leg; (2) papular syphilide of the scalp;; (3) deep ulcerations of tonsils and posterior pharyngeal wall; (4) stricture of the left nasal duct; (5) ulcers on forehead; (6) periostitis of nasal bones; (7) gumma of nasal septum, suppuration and perforation; (8) bursitis and synovitis; (9) periostitis of heads of tibiæ; (10) gummata of right testicle; (11) synarthrosis. The two noteworthy features of this case are the early appearance of the tertiary manifestations and their superficiality.

4. **Care of Nursing Breasts.**—Abbott shows how the breast is prevented from attaining normal development and thus secreting the normal amount of milk by the pressure of the ribs against the branches of the mammary artery as it passes out between the ribs. If the breasts are supported the circulation is normal and much more milk will be secreted. By lying on the nursing side while nursing the infant, the greatest amount of blood passes to the breast during lactation, and both the breasts should be nursed at each feeding, instead of alternately. Thus the breasts never hang flabby and will be firmer and of better shape, he asserts, after nursing is over.

13 Infancy of the Practice of Medicine and Surgery. H. Pomeranz, New York.
14 Cases of Intestinal Obstruction. L. G. Hanley, Buffalo, N. Y.

7. **Epilepsy in Relation to Menstruation.**—A study of twenty-three cases has convinced Gordon of the undeniable relation of epileptic seizures to menstruation; absolute freedom from attacks in the intervals between menstrual periods; apparently perfect integrity of the ovaries and still occurrence of epileptic fits immediately before or during menstruation; inability to control the fits with the usual bromid treatment; good, and even excellent effect of thyroid extract. The thyroid extract was given between the menstrual periods and bromids without thyroid only a few days before menstruation.

8. **Lobar Pneumonia in Children.**—Carr claims that inasmuch as lobar pneumonia is a self-limited disease of short duration, it seldom demands more than nursing and care. Medicinal treatment is needed when symptoms indicative of weakness or complications arise, and to relieve pain or restlessness. Bronchopneumonia in its acute manifestation may require no more treatment than is mentioned for lobar pneumonia, but as it is a disease that is usually, even in acute cases, associated with depressed vitality or infection, stimulation by alcohol and other agents will be required. In all cases of bronchopneumonia careful nursing and attention to diet will save many lives and lessen the extent and severity of the disease.

15. Abstracted in THE JOURNAL, July 17, 1909, p. 226.

18. **Neoplasms of the Kidney and Ureter.**—At St. Luke's Hospital, New York, for the past twelve years, there were, among 33,700 admissions, 325 cases of kidney disease (excluding nephritis), of which 24 were tumors, or 0.07 per cent. These 24 cases form the basis of Squier's article. In 13 of the tumor cases histologic diagnoses were made or confirmed. In 3 cases of cystic kidney and 1 of secondary carcinoma, the operative or bedside diagnosis could not be questioned. The other 7 are grouped as "tumors," irrespective of the clinical diagnosis. Pain was the first symptom in 7 patients; hematuria in 4, weakness in 5; tumor in 2; vomiting in 1, and pain and hematuria in 2. Thirteen patients died with recurrence: 10 at periods of one to twelve years; 1 patient had recurrence, but was living when reported; 1 died without recurrence five years after operation; 4 are living without recurrence (2 carcinomata, 2 hypernephromata). One reason of the high operative mortality is the rarity of early diagnosis. The tumor does not become palpable until it is very large. Radical removal at present offers the only chance for cure, the size of the tumor indicating the route for removal. The transperitoneal route permits better exploration of the opposite kidney and a more complete extirpation of the lymph nodes and other surrounding structures which may be involved in the growth.

24. **Cervical Cesarean Section.**—Cervical Cesarean section, according to Lewis, is a more difficult and longer operation than the older form; it requires deep dissection into extensive connective tissue spaces and admittedly in the probable presence of infection, it often involves considerable difficulty in extraction of the child and leaves the uterus in an abnormally fixed position. For clean cases, he says, it cannot replace the ordinary method; for cases of possible previous infection it offers no better chances than the classical operation with careful damming of the peritoneal cavity against the contents of the uterus and tight suturing of the uterine walls, while for cases of certain infection it cannot, he declares, replace craniotomy.

29. **Epithelioma of Vulva.**—Balloch reports two cases which show that irritating discharges from the uterus or vagina should not be neglected. *Any chronic irritation is liable to cause cancer.* Pruritus vulvæ calls for a careful search for its cause and its removal when found. The irritation incident to this disease may cause cancer of the vulva. The earlier the operation the better the chance of cure, and the more thorough the operation, the better the prognosis as to complete eradication of the disease. Even if the disease involves only one side, the glands on both sides should be removed and an effort made to determine the condition of the pelvic glands. Any involvement of the meatus urinarius or the urethra calls for careful examination of the urethra, supplemented by a cystoscopic examination.

36. **Head Injury.**—The analysis of 1000 cases of head injury observed by Phelps under similar conditions, could hardly fail to disclose some new facts in pathology and symptomatology, and to accentuate some others which were perhaps already known. The independence of the symptoms of cranial fracture and of intracranial lesions, the intervention of the sympathetic system in the production of symptoms of intracranial injury, and the relations of temperature to consciousness and in general to prognosis and diagnosis, are some of the more important of its disclosures; but the one fact of paramount importance which it demonstrates is that the essential lesion is the same in every class of intracranial injuries, and that it is a structural change in the cellular elements; that lacerations and hemorrhages are accidental, and not essential; that whatever influence these lesions may have in determining the more intimate pathologic condition they are but a part of a general contusion which may equally occur in their absence. This is the conclusion arrived at by Phelps, from the examination of every symptom in detail, focal as well as general, since in each instance many cases were found with no other gross lesion than a more or less well-pronounced circulatory derangement or even with no evident change at all.

38. **Surgical Conception of Pancreatitis.**—According to Smith, pancreatitis is of far more frequent occurrence than has been believed in the past. It is a disease progressive in its nature and tending to a fatal termination. With present methods it can be diagnosed without difficulty. It is, in the great majority of instances, secondary to and dependent on cholelithiasis or infection of the biliary tracts. It can be cured, or its progress stayed, by the early removal of its causes and the prevention of their recurrence. Its presence having been demonstrated, the immediate removal of its cause is imperative. Sodium phosphate, olive oil, neglect, delay, and optimistic indifference in the treatment of gallstones must give way to prompt, radical and efficient surgery.

43. **The Open-Seat Pelvic Binder.**—Newman describes pictorially a practical bandage for operations on the scrotum and testes and ilioinguinal region, which is said to possess the following advantages: The patient is not lifted; turning on the side is all that is required in applying the bandage. It is held in place by the spines of the iliac bones and does not tend to slip. The scrotum is not merely supported between the thighs but rests on the pubes. Urination is not interfered with; easy access to the rectum; defecation does not necessitate a change of the bandage. The bandage does not become *stringy and see-saw the skin of the entire region.* Inspection of the wound is easy and requires little more than the removal of a few safety-pins. After dressing the wound the same bandage may be reapplied; if the binder is soiled, it is laundered and re-used.

44. **Silver Foil in Surgery.**—Lewis says that on clean skin grafts the silver foil dressing is at its best and has replaced the older methods of wet dressings and gutta-percha, or the dry gauze dressings which present mechanical drawbacks. Under the foil the grafted skin remains fairly dry, as is the condition of normal skin. In plastic surgery, where cosmetic results are desirable, the slight secretion along the linear wounds passes through the crevices in the foil to be absorbed by the superimposed gauze, minimizing scab formation. In the usual clean wounds the possibility of infection from without is made more remote, especially in the groin, where the dressing may become wet with urine or slip and so expose the wound. In clean wounds, near a discharging wound, as in some secondary operations, the clean one may be protected against the other until union is established. The foil may be recommended on theoretical grounds to prevent subdural adhesions. In clean, rapidly granulating open wounds, the foil protects the delicate advancing margin of epithelium. Chronic ulcers, such as the varicose type, are not benefited. In the acute or painful stage of burns it is useless.

54. **Operation for Inguinal Hernia.**—The method devised by Duringer is really a modified Halsted and Bassini operation. The skin and superficial fascia are divided over the line of the inguinal canal. The external oblique aponeurosis is retracted and divided about one and one-half inches above and parallel with Poupart's ligament. The external oblique aponeurosis is dissected backward and upward. The lower segment is

dissected downward to expose the internal abdominal ring and the inguinal canal. The sac is liberated from the cord and opened. Excessive omentum is ligated and removed, and the stump and knuckle of bowel are returned into the abdominal cavity. The neck of the sac is liberated at the internal abdominal ring and ligated. The head of the threaded needle, with the same catgut, is passed through the upper angle of the wound, through the internal oblique and transversalis fascia and the stump of the sac drawn above the internal ring and anchored, making a so-called "bumper." This has the advantage of bringing healthy peritoneum in contact with the internal abdominal ring, giving it, necessarily, more strength. The cord is treated as the case demands. Duringer is not in the habit of removing veins.

In closing the abdominal anatomic layers, first, the cord is elevated by a gauze strip passed beneath it, and it is held out of the way. The curved fibers of the internal oblique and transversalis are stitched to the lower segment of the external oblique aponeurosis under the elevated cord. To prevent constriction and strangulation, Duringer seldom resorts to the outer stitch above and below the cord. Second, the superior segment of the external oblique aponeurosis is brought down over the cord, and over the line of union of the lower segment of the external oblique aponeurosis with the external oblique and transversalis, as low as possible, and attached by a mattress suture like the Mayo method of overlapping the aponeurosis for ventral hernia. Duringer then closes the superficial wound by a subcuticular catgut stitch. The advantage of this operation is said to be the maintenance of the exact anatomic relations of the abdominal wall.

56. **Angiotribe Method of Treating Hemorrhoids.**—The patient, having been previously prepared and the spinal injection made, is placed in Sims' position. The sphincter is gradually and thoroughly divulsed by making pressure with the thumb or fingers first in one direction and then in another, or with the Cook's speculum. The hemorrhoids are then exposed by everting the anus, and their number, size and location noted. The next step is also common to all methods, determining how many of the hemorrhoidal masses and what ones should be removed. This is best effected by firmly grasping each tumor with hemorrhoidal forceps and making traction so as to put the parts at its base well on the stretch. The angiotribe—Thuminn—is now adjusted; it will not only enclose the whole of the pile, but will reach up to the normal mucous membrane above, so that the vascular supply is wholly controlled. The portion of the pile that protrudes beyond the angiotribe is now cut off flush with the angiotribe by knife or scissors, just as in the cautery operation. The angiotribe is allowed to remain for 4 or 5 minutes, according to the size and condition of the pile. Pending the compression, the excised tumor, flush with the angiotribe, may be touched with a pledget of cotton saturated with pure carbolic acid. The angiotribe is then removed and reapplied as often as necessary; the most aggravated case never requiring more than four applications.

When the procedure has been completed there results a well and satisfactorily secured wound; the wound surfaces are in apposition. The perianal skin redundances have been in great part removed, and the traces of the operation then present to inspection two, three or more small compressed wound lines radiating from the anus, as the compressed stumps, when released, retain their linear form and return to the rectum in axial folds. These are gently returned within the sphincter and held in by a firm wedge-shaped gauze compress applied over the anus and firmly secured in place by a well-adjusted T-bandage. The patient is then placed in bed. The rectum should not be irrigated, nor any instrument introduced after the operation has been completed, from fear of tearing open the compressed wound. If the compression has been thorough, and if no dressing, packing or tubing of any kind is placed in the rectum, there will be little, if any, after-pain. The subsequent treatment does not differ from that commonly employed in any method of dealing with hemorrhoids.

69. **Eye Signs in Chronic Nephritis.**—The authors direct attention to the frequent occurrence of exophthalmos in chronic nephritis, and advance the view that the exophthalmos of chronic nephritis is analogous to that of exophthalmic goiter, being but one of a number of evidences of a chronic systemic intoxication. Among 33 cases of chronic nephritis seen during the first four months of 1909, 16 (48.4 per cent.) showed exophthalmos. The exophthalmos varied greatly in degree, as did the gravity of the nephritic process in the various individuals. Those cases presenting evidences of serious intoxication (suburemic or uremic symptoms) most frequently showed exophthalmos and one or more of the allied ocular signs—anisocoria, von Graefe's, Moebius', or Stellwag's sign. Exophthalmos has been an obvious sign in all of the patients with chronic nephritis which have died in the Johns Hopkins Hospital since Jan. 1, 1909, seven in number.

The authors also observed that the cases of chronic nephritis showing albuminuric retinitis during this period have invariably shown exophthalmos, with one or more other ocular signs. Exophthalmos is but one of several ocular signs which are frequently present in chronic nephritis. Widening of the lid slits (Stellwag's sign), dissociation of the movements of the ball and lids (von Graefe's sign), and the break of convergence of the eyes (Moebius' sign), may be present in a maximum degree in chronic nephritis without the thyroid showing any apparent involvement. The authors believe that the conclusion lies very near, that in both diseases a chronic systemic intoxication affecting the autonomic system is the causative factor in the production of the ocular manifestations. In their series of 16 cases von Graefe's sign was positive in 11 (68.7 per cent.). Stellwag's was positive in 13 (81.3 per cent.), and Moebius' sign was positive in 7 (43.7 per cent.). The pupils were noted as unequal in 5 cases (31 per cent.), and albuminuric retinitis was observed in 8 cases (50 per cent.). Exophthalmos was associated with arterial hypertension (pressure above 160 mm.) in 12 of the 16 cases and in 2 cases a maximum degree of exophthalmos was associated with the maximum arterial tension shown by the patient; as the blood-pressure fell the eyes became less prominent. The authors are not of the opinion, however, that the exophthalmos is due to chronic hypertension. It may exist independently and certainly only a small percentage of cases having arterial hypertension show exophthalmos. It is far more reasonable to assume that the arterial hypertension and the eye signs mentioned are but evidences of poisoning by perhaps separate toxins. It is well known that uremia may develop in a patient whose blood-pressure is not increased, and it seems probable that in chronic renal insufficiency several toxins are present in the blood manifesting themselves in various ways.

70. **Nature of Arteriosclerotic Process.**—According to Adami, the dominant primary event in the arteriosclerotic process—syphilitic, senile or functional—is a localized or it may be a diffuse weakening of the arterial wall and especially of the

media. This induces increased strain on the remaining coats; and if this be not excessive, that strain leads more especially to connective tissue overgrowth and the development of the characteristic lesions of arteriosclerosis.

71. **Discharge of Food from the Stomach.**—The purpose of this investigation was to determine as accurately as possible under otherwise normal conditions, the influence of some of the commoner physical, chemical, and biologic factors on the movements of the stomach and on the rate at which it discharges food into the intestine. The method employed was that used by Cannon in studying the passage of different foodstuffs from the stomach. The food used, except when otherwise specified, was 25 c.c. of mashed potato, with which was mixed 5 grams of subnitrate of bismuth. The consistency, which depends on the amount of water added, was always as nearly uniform as could be judged by the eye and by manipulation. Full-grown normal cats, deprived of food for twenty-four hours previous to the experiment, served for observation. In all the experiments, except those with fluid food, the animals were placed on the holder and fed from a spoon with no special difficulty. At regular intervals after feeding, observations were made by means of a fluorescent screen illuminated by the *x*-rays; and the dark shadows made by the food were traced in outline on transparent paper laid over the screen. The aggregate length of these shadows measured the relative amount of food in the intestine at the different times of observation.

Hedblom and Cannon found that if carbohydrate food is thinned by adding water, there is, within limits, very little change in the rate of exit from the stomach; but adding water to protein food tends to make the discharge more rapid. When hard particles are present in the food the rate of outgo from the stomach is notably retarded. Coarse, branny food leaves the stomach slightly faster than similar foods of finer texture. The presence of gas in the stomach delays gastric discharge, an effect due to the gas preventing the walls of the stomach from exerting the normal mixing and propelling action on the food. No considerable variation from the normal rate of exit from the stomach is observed when the food is fed very hot or very cold. Food with approximately normal acidity leaves the stomach much faster than food which is hyperacid (1 per cent.), a result in harmony with other observations on the acid control of the pylorus. Feeding acid food is followed by deep and rapid peristalsis. Massage of the stomach, even when extensive, has very slight influence on the passage of food through the pylorus. Irritation of the colon (with croton oil) notably retards gastric discharge and delays the movements of food through the small intestine.

72, 73, 75. Abstracted in The Journal, June 5, 1909, pp. 1865, 1866.

76. **Location of Cardiac Apex Beat.**—Dayton claims that the point of maximum impulse frequently does not define the site of the cardiac apex. The point of maximum impulse, either visible or palpable, may be produced by a portion of the heart wall at some distance from the apex. Except in cases in which the visible and palpable impulses coincide, as they usually do with a normal heart, it is better to state simply that pulsation is visible in certain interspaces at a given distance from the median line. It is frequently impossible to determine the left border of the heart by percussion, on account of the changes in the resonance of the adjoining area due to large breasts or intrathoracic conditions, or when the apex is carried so far toward the left by hypertrophy or by displacement of the heart, as a whole, that percussion, unless extremely light, tends to bring out dulness of the lateral surface of the heart. Auscultation, as a means of locating the apex, is at best a makeshift in the event of the failure of the other methods. The most valuable clinical method of locating the cardiac apex is the palpation of its impulse when this can be detected in an interspace. The apex beat should be considered as the point farthest downward and to the left at which a distinct forward thrust of the heart can be felt. The clinical apex so located, being close to the anatomic apex, is of real value in estimating the size or relative position of the heart. Because of the influence of posture on the area of relative cardiac dulness, and the situation of the apex beat, it is advisable, for comparison with subsequent observations, to record whether the patient was examined in the erect or in the dorsal recumbent position.

77. **Orthodiagraphy of the Heart and Great Vessels.**—While orthodiagraphy should not be looked on in any way as a substitute for the other well-known methods of examination of the heart and great vessels, Claytor and Merrill say that it is at the same time a valuable aid. It can be used to make fairly accurate outlines and measurements of the heart and great vessels, thus enabling one to make comparisons with the normal or with subsequent diagrams of the same case. The use of the orthodiagraph may also serve to prove whether or not the size of the heart is influenced to any appreciable degree by a single effort of exertion or by a single therapeutic or gymnastic treatment.

78. **Acute Leukemia.**—Ottenberg observed that the rods described by Auer can be found in many cases of acute leukemia. They have never been found in any other disease, and there is no evidence that they are parasites.

91 Eclampsia. L. W. Armstrong, Breckenridge, Minn.

90. **Tumors of the Breast.**—The point emphasized by Judd is that the surgeon can promise a definite cure in the majority of cases in which the patients present themselves for treatment on the appearance of first symptoms. As the technic develops, and physicians have a better knowledge of the extension of the growth of the tumor, they will be able to cure a larger percentage of the advanced cases. Therefore, an early operation, even though badly done, will effect more cures than will a perfect operation which is performed late. Furthermore, in order to get malignant cases early, it is necessary to remove all tumors as soon as they are discovered, as many of the doubtful and some of the supposedly benign cases will eventually prove to be malignant.

100. **The Pus Appendix.**—Green says that the definition of pus appendix is: Any pus inside or outside the appendix caused by the appendix. This will include most of the really acute and some of the chronic cases of appendicitis. The disease occurs at all ages, but is most common from 12 to 30. The three cardinal symptoms are pain, localized tenderness and resistance. The only treatment is removal of the cause, and the sooner this is done the better the patient's chance for a speedy recovery.

103. Published in the *Kentucky Medical Journal*, Oct. 1, 1909.

106. **Inflation of Lungs.**—In a series of eighteen experiments the following routine was carried out by Capps and Lewis: A dog was chloroformed until both respirations and heart beat ceased from one to three minutes. Then a hard rubber tube was slipped through the larynx into the trachea, and by means of a pump air was forced 15 to 20 times a minute into the lungs. A T-tube in the rubber connection provided for the escape of air between inflations and also controlled the pressure of air during inflation. No precaution was taken to filter the air. In addition to this artificial respiration rhythmical pressure over the heart was often practiced. In unresponsive cases 15 minims of a 1 to 1,000 solution of adrenalin were injected directly into the heart itself to provoke the muscular contractions. These efforts at resuscitation were successful in thirteen of the sixteen cases. One to three weeks later these animals, with one exception, were in good health. Postmortem examinations were then made and the lungs examined in gross and microscopically. Capillary hemorrhages were present in two cases. Half the cases showed a marginal emphysema of moderate degree. This seemed to cause no inconvenience to the animals. Pneumothorax was never present. Infection of the lungs or pleura did not occur in any case.

112. **Undescended Testicle and Appendicitis.**—Cantwell reports four cases to show that one cause of undescended testicle is appendicitis in the fetus. The right testicle is more often retained than the left. In every one of these cases the left testicle was normal. The mildest inflammation might cause a cobweb adhesion, enough to stop the descent of this organ. Adhesions are frequently found in the peritoneum of the fetus. In the first three cases the position of the testicle just beneath the appendix was suggestive of the cause of the ailment.

113. An abstract of this article appears in the report of the Mississippi Valley Medical Association.

114. **Chronic Nephritis.**—Connors does think that any surgical treatment can do good in chronic Bright's disease, but in cases of uremia, anuria, or any other acute attack of poisoning consequent to arrest of kidney function, we can help by surgical interference, to be used only after medical aid has failed. If surgery is to be employed, nephrotomy is the operation of choice. It is his belief that decapsulation of the kidney in chronic nephritis is not a logical procedure.

128. **Bone Transference.**—In May, 1902, the patient, then 6 years of age, was treated for acute infection—osteomyelitis of the tibia. The middle portion of the shaft of the tibia was completely destroyed. The tibial defect was supplied by carrying the divided end of the middle portion of the fibula across to the tibia, countersinking it in the upper remaining fragment of the tibia, thereby securing union. The result of the first operation was highly satisfactory and the patient was allowed to walk, bearing his weight on the lower end of the fibula in its normal position. At this time there was manifest hypertrophy of the shaft of the fibula. Very soon, however, it was noted that there was a decided lateral bowing of the foot on the fibula, causing a deformity. Accordingly, six months after the first operation, the fibula was again divided at a point opposite the upper end of the lower segment of the tibia. With little difficulty the transference was completed. Again the wound healed kindly and rapid union was obtained. In six weeks, the child began to walk with little, if any limp, and in this respect the condition has improved, until, at the present time, he walks with a limp; runs as other boys do, plays baseball, football, and, in fact, is walking on a leg which is comparatively as useful as the other. The radiogram demonstrates that the fibula has assumed the dimensions of the normal tibia. Joint function at both knee and ankle remain perfect and there is but slight, if any, limitation of leg rotation.

4. **Formalin-Iodin Catgut.**—For about two and one-half years Steward has used formalin-iodin catgut. This is ordinary commercial formalin catgut, made up into short skeins (each skein containing about the right quantity for one operation), and steeped in a 1 per cent. solution of iodin in water for ten days. It is usually sterile in five days, but Steward steeps it for ten to be certain. At the commencement of the operation, skeins of the sizes required are picked out of the stock jars with sterile forceps, and placed in carbolic acid (1 in 20) till needed. This dissolves out the excess of iodin, which might possibly cause irritation. This gut is very strong, although after it has been kept for several months the very fine sizes become brittle. It is very resistant, and consequently there is *no fear of too rapid absorption.* It is beautifully smooth, uniform in diameter, inelastic and delightful to handle.

5. **Edema of the Face and Mucous Membranes.**—Adam reports 2 cases. In the first case the swelling began at the inner canthus of the left eye, and slowly increased, involving the cheek and the side of the nose; finally solid edema extended from eye to mouth, and from the nose over the whole cheek; it caused the patient much mental misery, owing to the disfigurement. There was no pain or tenderness, but occasionally a feeling of heat and a red flush; the edges of the nostrils, especially the left, were covered with thick hard crusts; the mucous membrane of both inferior turbinals was much thickened, that on the right showing a growth, like a small cherry, occluding the nostril. The tissue of the soft palate and uvula was much thickened; adenoids were still present. The treatment adopted was the removal of crusts in the nostrils with hydrogen peroxid, followed by application of silver nitrate dissolved in sweet spirits of niter, and by an ointment; reduction of turbinal hypertrophy, removal of adenoids and tip of uvula; application of mercurial ointment to cheek, overlaid with absorbent cotton and a firm elastic bandage; iodids and a thyroid preparation internally. After two months the edema disappeared and remained cured; there is still slight thickening of the soft palate and inferior turbinals.

The other patient had had chronic edema of the left cheek, upper lip and the left lobule of the nose for four years; had attended several hospitals and seen nine physicians. The edema, especially that of the upper lip, was very disfiguring. Crusts were found inside the left nostril, and an ulcerated groove down the center of the mucous surface of the upper lip, due to the sharp and carious edges of the everted central incisors. The treatment adopted was similar to that in the first case, with a similar result. Adam points out (1) that the disease is a local and not a constitutional one; (2) that, *so far as the face is concerned, the primary lesion is probably always one of a mucous membrane,* or more usually of a mucous orifice; (3) that the edema may affect the mucous membrane as well as the skin; (4) that the condition is curable.

12. **Unusual Cases of Echinococcus Cysts.**—Syme reports a number of rather unusual cases, in some of which the symptoms closely simulated those of gall-stones. Rupture of the cyst eventually led to the making of a correct diagnosis. In one case the cysts were located in the ilium; in another the cyst was in the muscles of the back, to one side of the spine, which communicated with a second cyst in the chest. In a third case, cysts were present among the spinal muscles, the vertebræ were eroded, and cysts had also formed between the laminæ and dura mater. Treatment consisted of enucleation of the cysts.

16. **Enucleation of the Prostate.**—In Freyer's series of 644 operations of enucleation of the prostate to date, there have been 48 octogenarians, ranging from 80 to 89 years, and 9 bordering on this period, aged 79, with 6 deaths. The average age of all his patients is 69 years, the prostates weighing from one-half ounce to 17 ounces, with an average of 2½ ounces. In connection with these 644 operations, there have been 39 deaths, in periods varying from six hours to thirty-seven days after operation, or a mortality of 6.05 per cent. The mortality has been gradually diminishing from 10 per cent. in the first 100 cases to 4.24 per cent. in the last 200. The causes of death were: Uremic symptoms due to chronic kidney disease, 16; heart failure, 6; septicemia, 2; shock, 4; exhaustion (kidneys much diseased), 1; mania (hereditary in one), 2; malignant disease of the liver, 2; heat stroke, 1; pneumonia, 1; acute bronchitis, 2; pulmonary embolism, 1; and cerebral hemorrhage with paralysis, 1. In 114 cases vesical calculi were removed at the same time; but all the deaths in these cases are accepted in connection with the prostatectomy, none being put down to the suprapubic lithotomy involved.

17. **Diagnosis of Cancer by Blood Examination.**—The *finding* of a normal antitryptic content in any cases in which the

question of malignancy has arisen appears to be of the greatest value in excluding a diagnosis of cancer. Unfortunately, the positive value of a negative diagnosis is not absolute, since the test was of no value in 6 cases out of 100 examined by Hort. The finding of a raised antitryptic content in any case in which the question of malignancy has arisen does not justify a positive diagnosis of the presence of cancer, since Hort found constantly a raised content in measles, scarlatina, intestinal tuberculosis, acute septicemia, some cases of leprosy and syphilis, and a similar rise will also almost certainly be found in many other infections, as well as in certain autoinfections, such as nephritis. In spite of this, however, a raised antitryptic content often appears to be of great value in deciding a doubtful opinion as to the presence of malignant disease, since the greatest incidence of cancer is at the period when the infective incidence (hetero-infection) is at the lowest.

In the absence of obvious infection, the possibility that a raised antitryptic content may sometimes be due to autoinfection from non-malignant cell aberration must constantly be borne in mind. A raised antitryptic content appears to be of the greatest value in distinguishing between an innocent neoplasm and a malignant one.

31. **Pathology of Lead Poisoning.**—Goadby and Goodbody are of the opinion that the essential and primary action of lead intoxication is the production of minute and microscopic hemorrhages in various portions of the body, including the nervous system; and that the clinical symptoms of lead palsy, and its good prognosis when treated early, are explainable by the presence of minute hemorrhages in the peripheral nerves. The presence of these minute hemorrhages in the nervous system also gives an explanation of the varied pathologic findings of many previous workers.

36 *Hereditary Sudden Death. A. Gilbert and A. Baudouin.

36. **Hereditary Sudden Death.**—Gilbert and Baudouin discuss instances of sudden death in persons who may or may not have presented premonitory attacks of syncope, and which is due to an hereditary disposition. In these cases there is a sort of diathesis, the diathesis of sudden death. Sex appears to possess a certain influence. The authors' inquiry bore on fourteen persons who had died suddenly, and of this number eleven were men and three were women. The age at which the fatal syncope took place oscillated between 20 and 62 years. Speaking generally, the incidence of sudden death is earlier in the descendant than in the ancestor by whom the diathesis was transmitted. The underlying cause of the diathesis is heredity. In most of their cases this can only be traced 1 degree, from father to son. In 2 cases it was traced back 2 degrees. Independently of heredity, Gilbert and Baudouin's investigations brought to light many and various predisposing causes. Some of them, supervening only a short time before the final syncope, played the part of accidental causes. These, indeed, are anything but constant, for in several instances nothing whatever could be discovered. In one, a person free, so far as known, from disease and previously in excellent health, fell dead while out walking; similarly in the case of a man, who all at once felt queer, went to bed, asked for something hot, and expires forthwith.

In all are found traces of the same diathesis, and the authors suggest that this may help to explain many cases of death under chloroform. Patients suffering from very mild attacks of typhoid fever sometimes die unexpectedly, and here, again, it would be well to inquire into the family history. One of the most interesting points, possibly the most important of all, is the supervention of periodic attacks of syncope before the fatal one. In other cases the syncopal tendency was less marked, and in some it is distinctly stated that none had ever occurred. In these cases, apart from the morbid heredity and the habitual pallor of the patient, sometimes noted, there is little to note. Death may not be preceded by any premonitory signs. One patient fell dead in the street, another when out walking, and the body of a third was found in bed with the bedclothes undisturbed and a calm look on his face. Sometimes, however, the patient experiences a vague malaise, he groans, asks for something to drink, turns and twists himself about, but in all death is sudden, not the death that follows cerebral hemorrhage, but death due to arrest of the heart.

45. **Puerperal Convulsions.**—Little says: Minimize the use of narcotics and anesthetics. Chloroform is rarely indicated for the control of convulsions, but should be used when general anesthesia is required for examination or delivery. 2. Immediate delivery is advisable, particularly when the child is viable. 3. In the majority of cases the onset of labor is more or less intimately associated with the onset of convulsions; *accouchement forcé*—preferably Harris' method followed by version—has given the best results. 4. Immediately after delivery, if not before, the stomach should be washed out, and several ounces of magnesium sulphate, well diluted with warm water, should be introduced through the tube. The patient should then be sweated by means of a hot-air bath or hot pack. 5. If convulsions recur after delivery, and particularly in postpartum eclampsia, the best results are obtained by withdrawing from 700 to 900 c.c. of blood from one of the veins of the forearm. 6. A large quantity of fluid (forced fluids) should be given for several days, and the amount so given should be tabulated carefully for comparison with the amount of fluid eliminated in the urine and stools. If the excretion is inadequate, repeat the sweating and purgation. Do not allow the patient to become waterlogged. 7. Careful records of ingestion and excretion should be kept for at least ten days, as the involution of the uterus has a marked effect on the general metabolism, particularly between the sixth and ninth days.

58 *Abnormality of the Gall-Bladder. H. C. Hinder.

56. **Treatment of Innominate Aneurisms.**—Haynes tied, simultaneously, the right common carotid artery and third part of the subclavian artery in a man, aged 42. The patient made an uninterrupted recovery, the wounds healing by *first*

intention. The radial pulse was fairly established at the wrist, the congestion and edema had gone from the arm, pain, thrill and pulsation had ceased in the tumor, the aneurismal bruit had gone, and the patient's cough was much improved. He expectorated blood-tinged mucus for a while, and the râles in the right chest were very few. Three months afterward there was no pain or difficulty in breathing, the tumor was decreasing in size, and there was no pulsation, thrill or bruit. The man had good use of his arm, and wanted permission to go to work, felling trees with an axe. He resumed his former hard work and suffered no inconvenience.

58. **Abnormality of Gall-Bladder.**—In one case Hinder found a septum which divided the gall-bladder into two unequal parts. This septum was thin and extended about half way up the fundus. It was placed transversely parallel to the under surface of the liver. There were stones in the main portion, which held direct communication with the cystic duct, and there was one small flat stone in the smaller division. In the second case no gall-bladder was to be found at first, but careful search disclosed a tiny gall-bladder about an inch long and as large as the terminal joint of the little finger. The wall was much thinner than that of an ordinary gall-bladder, and it contained several very small calculi. In the third case there was absolutely no sign of gall-bladder or gall-bladder fissure, merely a little dimple at the edge of the liver. There were no adhesions, but a falciform band of tissue about 1¼ inches in length, stretching from the liver to the peritoneum covering the bile duct, hepatic artery and portal vein. The common duct was clear. The pancreas was enlarged and somewhat hard. Both of these two men claimed to have rather poor digestion.

59 Human Milk Drawn and Fed to Infants. (La tétée artificielle.) V. Wallich.
60 *Vomiting of Pregnancy. (Des vomissements de la gestation.) A. Pinard. Commenced in No. 7.

60. **Vomiting of Pregnancy.**—Pinard presents a historical sketch of the subject from Hippocrates to date. In his experience with 843 cases the primiparæ predominated; in 72 per cent. the vomiting commenced early and lasted for about three months, finishing before the end of the fourth month; in 28 per cent. the vomiting continued for five months and more, and in 5 per cent. throughout the entire pregnancy. In 19 out of 127 cases of hydatid mole vomiting occurred and always of exceptional severity. He never observed fever with the vomiting, but the pulse was frequently modified, and sometimes within wide limits in the same woman at different hours. When the pulse is over 100 the organism is suffering from loss of water, the urine becomes scanty and respiration is rapid and shallow. Constipation is the rule and there is extreme thirst. The tongue is very red, as if varnished, and, with or without hallucinations or tendency to syncope, coma ensues and the woman dies without ever having presented a higher temperature except during the last hours. In some cases the vomiting ceased two days before death. The uterus is generally rather smaller in these toxic vomiting cases, probably from the excessive loss of fluids, and the walls are flabby, sometimes leading to rejection of the idea of a pregnancy. Even when the uterus has been artificially evacuated and the organism resupplied with fluids, the acceleration of the pulse may persist for some time, after cessation of the vomiting, sometimes as long as for three weeks after the uterus has been emptied. He has noticed that these women lose weight as pregnancy progresses; this was noticeable in 42 per cent. of his cases. All these facts observed have convinced him that the vomiting is a sign of intoxication, and that, as a rule, the organism conquers this intoxication, but it may be so severe as to lead to a fatal outcome; the most constant, the most easily supervised and at the same time the most serious reaction is the acceleration of the pulse. He is inclined to assume that the pregnant organism generates some poison during the first half of the pregnancy, which has a special action on the vomiting center and causes, first, hypotension and then acceleration of the heart. Another poison seems to be generated during the last half of the pregnancy which acts also on the vomiting center, but induces hypertension and a tendency to convulsions. The liver is probably concerned in the production of these toxins, but the principal part, he believes, is played by the corpus luteum, which during pregnancy is larger than the hypophysis. In some cases the vomiting persists even after subsidence of the cause, from what he calls the *aptitude vomitive individuelle*, and in these cases suggestion may arrest the tendency to vomit. But when the intoxication still persists, suggestion alone is impotent, and treatment must be directed to eliminate the toxins, relieve the liver and kidney functioning, and prevent further autointoxication by restricting the patient to a milk-vegetable diet. So long as the pulse is under 100, the toxemia is not so excessive as to require interruption of the pregnancy, but he advises this at once when the pulse goes over 100. Delay may be fatal, or, at least, may expose the patient to the danger of paralysis. In 5 of his cases neuritis with atrophic paralysis developed later. Saline transfusion before, during and after the evacuation of the uterus is a useful adjuvant, and no food should be allowed until the woman can take considerable quantities of water by the mouth without vomiting. Water and milk should be all that is allowed until the pulse is permanently normal once more. He has witnessed serious symptoms develop after ingestion of an egg before the pulse rate was normal. In conclusion, he gives the details of 16 cases of uncontrollable vomiting in his experience since 1902, in which treatment was on these principles, the results justifying his assertions.

61 *Immunization of Cattle Against Tuberculosis. (Recherches sur l'immunisation antituberculeuse.) H. Vallée.
62 Mechanism of Action of Arsenic Derivatives in Trypanosome Infection. (Mécanisme d'action des dérivés arsénicaux dans les trypanosomiases.) C. Levaditi.
63 *Rabies at Constantinople. (La rage et le traitement antirabique à Constantinople.) P. Remlinger.

61. **Immunization of Cattle Against Tuberculosis.**—Vallée here presents the conclusions of six years of extensive research in this line at the state veterinary college at Alfort. About 166 grown cattle and 500 calves were utilized in the experiments; the best results were obtained with intravenous inoculation of living tubercle bacilli of a much attenuated strain derived from a horse. The slight virulence of this strain and its complete absorption after inoculation are important factors in the results obtained. Inoculation with killed bacilli never produced satisfactory results. Ingestion of the cultures by the mouth conferred temporary immunity, the more complete the younger the animal. Vaccination by the mouth, as he calls this method, permitted the young cattle to resist for a year close contact with other cattle with open lung tuberculous lesions, and even after two years of this intimate intercourse with infected animals, they presented only insignificant or hidden lesions, while the control animals showed signs of severe and advanced tuberculosis. This vaccination by the mouth of the young cattle, he affirms, supplemented by the search for and elimination of all cattle with open tuberculosis, opens a prospect for a simple, safe and certain method of eradication of tuberculosis from cattle. The full details of his research will be published in the transactions of the recent International Veterinary Congress which was held at The Hague in September.

63. **Comparative Rarity of Rabies at Constantinople.**—Remlinger estimates the number of vagrant dogs in Constantinople as between 60,000 and 80,000, and yet, he states, rabies is comparatively rare. Only 49 dogs were brought to the public pound on account of rabies, in 1908, and of the 978 persons applying for treatment at the Ottoman Pasteur Institute in 1908 all but 157 of the patients came from regions outside of Constantinople and its suburbs. The rabies virus at Constantinople, however, seems to display unusual virulence when infection does occur. The dogs possess no natural immunity, but are distinguished by the fact that they keep strictly to their own territory, the dogs of one section of the city never venturing into another section, or, if they do, they are torn to pieces by the dogs of the section into which they intrude, while all live in peace when certain arbitrary boundaries are respected. On this account, when rabies does develop in one

section it never spreads to another. A further prophylactic factor is the instinctive avoidance by the dogs of one of their number who is sick with rabies. He is avoided and forced back into his lair if he attempts to come out. This instinctive prophylaxis among dogs is observed everywhere and explains why rabies does not spread more, but remains limited to the section where it first develops. At Constantinople the sections to which the dogs confine themselves are sometimes not more than 150 feet long, and generations succeed each other without ever passing beyond its boundaries. Remlinger estimates that fully 100 dogs die every day at Constantinople, but the birth-rate keeps pace with the mortality or exceeds it.

64 *Urine Reaction for Diagnosis of Incipient Tuberculosis. (L'uro-réaction, diagnostic précoce de la tuberculose.) F. Malmejac.
65 Apparatus for General Anesthesia with Ethyl Chlorid. P. Rosenthal and A. Berthelot.

September 25, No. 77, pp. 673-680

66 *Intoxication from Cheese. (Intoxications par le fromage.) A. Fonteyne.

64. **Reaction in Urine in Incipient Tuberculosis.**—Malmejac has been making a special study for ten years of the acidity of the urine in tuberculosis, having found that it differs from normal urine in respect to the persistence of the acidity. Urine from a healthy individual not taking medicine retains its acidity on standing not longer than from three to ten days, while urine from the tuberculous, under the same conditions, retains its acidity for twelve days at least and up to three months or more. Comparison with other affections that might be confused with tuberculosis confirms this practically exclusive persistence of the acid reaction in tuberculosis for an unusually long period. The reaction persists longer, also, the more advanced the tuberculous process, averaging seventeen days for tuberculosis of the first degree, twenty-six for the second, and forty for the third. The acidity may be determined by adding 3 drops of a 1 per cent. solution of phenolphthalein to 10 c.c. of urine diluted with 50 c.c. of distilled water, strictly neutral, in a dish with a flat bottom. The titration is done with decinormal solution of sodium hydrate; the findings represent the proportion of sulphuric acid to the liter. An increase in the acidity of the urine, on standing, is frequently observed in diabetes, but a prompt decrease in the acidity of normal urine is the rule, and the durable level plateau of the curve in tuberculosis is a characteristic phenomenon observed in 97 per cent. of all the tuberculous individuals he has examined, often even before clinical signs of the disease became apparent.

66. **Intoxication from Cheese.**—Fonteyne reports an epidemic of gastrointestinal disturbances affecting forty persons who had partaken of a certain cheese, and bacteriologic and experimental research disclosed a special cocco-bacillus, not resembling the paratyphoid group.

September 29, XXIX, No. 39, pp. 457-468

67 *Determination of Primary Focus in Generalized Cancer. (Détermination du foyer primitif dans les tumeurs malignes généralisées.) B. Huguenin.

67. **Determination of Primary Focus with Generalized Malignant Disease.**—Huguenin has witnessed a number of cases in which the metastatic tumors rapidly grew to large proportions while the primary growth was small. In one case the primary tumor on the back of the hand was no larger than a nut, while the metastatic tumor in the axilla rapidly grew to the size of an orange. The discovery of an embolus in the center of a tumor confirms its secondary nature; it is frequently possible to locate the primary growth by the structure of the cells in the embolus. In a recent case of this kind he declared that the carcinoma in the bone must be secondary to a primary tumor in the liver or suprarenals, and autopsy later revealed it in the liver. When a carcinoma develops in an organ not containing epithelium, it is wisest to assume that it is a secondary growth. The same applies to a cancer in which the epithelial cells do not correspond to the cells of this kind normally in the region. A crater-like depression is characteristic of primary cancer in the stomach, but cancer of the liver never presents this form, he says, unless it is secondary. A primary liver cancer is knobby; there is no depression in the center and the nodule may have a diameter of 10 or 20 cm., while the secondary carcinoma rarely exceeds 4 cm. in diameter. Carcinoma in other organs, especially the esophagus, is primary when it presents the crater form; the secondary growth generally develops underneath the mucosa and merely lifts it up without forming part of it.

69. **Hemostasis with Constricting Belt in Obstetrics.**—Sigwart writes from Bumm's clinic at Berlin to report some new cases, bringing the total to 24, in which the Momburg technic was applied to arrest threatening postpartum hemorrhage. The experiences were extremely favorable, and there were no serious by-effects of any kind; in several cases the women bore the constriction without general anesthesia. The rubber tube is wound two or three times around the waist and drawn tighter until the hemorrhage stops. The simplicity of the procedure and its immediate effect commend it, he asserts, for general adoption in obstetrics, for which it is better adapted than for gynecology. He declares that clinical observation and post-mortem findings have confirmed the harmlessness of the procedure, and as no special skill is required for it, he advocates its use in urgent cases while awaiting the arrival of the physician. As the only failure consists in not drawing the belt tight enough, he gives a picture to counteract the natural dread of this procedure, showing a woman with the belt applied arresting postpartum hemorrhage. (The technic was mentioned in THE JOURNAL, Nov. 14, 1908, page 1742.)

74. **Autogenic Puerperal Infection.**—In Schmidt's bacteriologic examination of 100 cases before and after childbirth, virulent streptococci were not found in any instance before delivery, and yet of the patients 20 had a febrile puerperium.

75. **Spinal Anesthesia and Its Influence on Labor.**—Westermark has been continuing his research on the influence of anesthetics on labor, and here reports 19 cases in which 0.08 gm. stovain was injected for spinal anesthesia during labor. The effect revealed some interesting physiologic facts, but did not suggest that the technic was as suitable for obstetric purposes as chloroform, which is much simpler to use and less dangerous.

76. **Physiology of the Amniotic Fluid.**—Wolff gives the details of a long series of experiments which have established beyond question, he thinks, that the amniotic fluid is not a product of the mother. The fetus is the exclusive and direct source of the amniotic fluid.

77. **Operative Treatment of Puerperal Peritonitis and Phlebitis.**—Leopold has previously reported 16 cases of acute puerperal peritonitis in which prompt operation saved twelve of the women, and 2 cases of thrombophlebitis in which one of the patients was saved by ligation of the ovarian veins, the third day after the first chills. He here reports another case of acute peritonitis in which the patient was saved by suturing a ruptured point in the small intestine, the day before delivery. The case confirms the advantages of laparotomy for peritonitis if not more than 2 days old, while the resistance is still good and before the intoxication is too severe. In 2 other cases, purulent thrombophlebitis after delivery was treated by ligation of the ovarian veins, but in both the intervention came too late. In one the source of the pyemia was evidently the suppurated site of the placenta, and early panhysterectomy might possibly have saved the patient. In the second case gonococci had evidently penetrated from the vagina into the veins of the paravaginal tissue, with inflammation of the veins in the right groin and secondary thrombosis of the iliac veins and vena cava. The mistake was made that the vein in the groin was not incised and evacuated when its swollen condition first attracted attention, the fifth or sixth day. The reliance on expectant treatment proved vain. When puerperal thrombosis is accompanied by a rising temperature or a pulse curve which slowly subsides again, the prognosis is favorable, but not when there are remittent high fever and chills. This indicates always some localized pus focus. If the pus cannot escape outward, or if it is in an ovarian or iliac vein, it empties into the vein above, and this must be prevented at all hazards; this is possible only by early search for and evacuation of the pus focus. The thrombi may pass into the vena cava early and the germs penetrate the vessel wall, the resulting inflammatory edema soldering veins and arteries together. In the last case this was responsible for his mistaking the hypogastric artery for the thrombosed vein. The attempt to ligate the iliac vein proved impossible, as it could not be separated from the artery. The lesson from his 21 cases, he says, is to operate and operate early, but never too late.

78. **Tuberculin Treatment of Pulmonary Tuberculosis.**—Pel read this article at the recent international medical congress, concluding his remarks with the statement that tuberculin is still in the period of trial. He has been unable to acquire much enthusiasm for it. There are so many unaccountable by-effects, such as headache, fever, insomnia, rheumatoid pains, loss of appetite and weight, acceleration of the pulse and general depression, while acute exacerbations or complications of the tuberculous process may be encountered, as also an individual hypersusceptibility to tuberculin. The course of treatment is so long, so complicated, the indications are so restricted and there are so many contraindications, that he declares that failure to institute tuberculin treatment is not a sin of omission, for the present. The clinics, hospitals and sanatoriums should make a point of comparative and critical study of tuberculin treatment to place it on a solid basis.

83. **Early Sign of Arteriosclerosis.**—Engel calls attention to the differential importance of variations in the blood pressure in different vascular areas. The systolic blood pressure is the expression of the effort of the heart plus the elasticity of the vessels. If there is mechanical obstruction in the vessels, the blood pressure in the area will be proportionately reduced. A circumscribed arteriosclerotic process causes the blood pressure in the region to become much lower than in the area on the other side. The variation is slight, not more than from 5 to 15 mm. mercury, and it may not be evident to the finger, but it can be readily measured with the tonometer. The difference has diagnostic importance only when it is found constant on repeated examination. Consequently, if a constant difference of 5 mm. is found in the pressure in the right and left arm, for instance, this is an essential aid for the diagnosis of arteriosclerosis. This finding is also important for differentiating primary nephritis from arteriosclerosis. In nephritis the cause of the increased blood pressure acts uniformly throughout the body, and local disturbances do not occur in single vascular areas, as in case of arteriosclerotic lesions in the walls of the vessels.

87. **Scrofula.**—Escherich remarks that the cutaneous Pirquet tuberculin reaction and scrofulous skin lesions—scrofulides—are influenced alike by injections of tuberculin. This cutaneous test has shown the connection between the non-bacillary manifestations of scrofula and tuberculosis. The true cause of scrofulous changes in the skin is the hypersensitiveness of the skin and mucosæ resulting from the presence of the antibody, that is, the tuberculous "allergy." The difference between the toxic and the bacillary symptoms of tuberculosis has long been recognized, and is a reason for maintaining the term "scrofula" or "scrofulide" to express the tuberculo-toxic changes in the skin. The term "scrofula" he would retain for those cases of tuberculosis in which the focus is latent and there are merely the lesions known as "scrofulides." If signs of a manifest bacillary focus are present also, he would call this "scrofulo-tuberculosis." Pure scrofula is the most harmless form of tuberculosis in children. A complete cure is the rule, and it confers relative protection against later infection. This also applies to some extent to scrofulo-tuberculosis. It may be obstinate, but it is generally benign. The discovery of the typical scrofulides is thus important for both prognosis and treatment. He discusses the connection between the status lymphaticus and scrofula, accepting some congenital constitutional anomaly, manifested by the former, as the basis for the development of the scrofulous symptoms in the course of tuberculosis. The article, which was presented as an address at the recent international medical congress, emphasized the importance of tuberculin in treatment of scrofula, to supplement the usual measures.

88. **Treatment of Hydrocephalus by Puncture of the Corpus Callosum.**—Bramann has applied this method of treatment in 22 cases, including 8 of hydrocephalus. He aims to relieve the pressure on the brain by perforation of the corpus callosum to establish a broad communication between the fluid in the ventricle and the subdural space of the brain and spinal cord. He assumes that the active flow of the fluid between the ventricle and subdural space will prevent the opening from growing up. For children it is unnecessary to trephine, as a curved cannula can be inserted through a small incision in the dura, close to the sinus, after incising the skin about the middle of the anterior fontanelle, 1 cm. to the right of the median line. The cannula is then pushed in between the wall of the sinus

and the surface of the brain toward the median line until the tip of the cannula reaches the falx and glides along this to the corpus callosum, through which it is pushed. After allowing escape of fluid, which is generally under high pressure, the cannula is worked to and fro until the hole is sufficiently enlarged to ensure its remaining open; then the cannula is removed. In his 8 cases of hydrocephalus the improvement was marked, the fontanelle no longer protuding, but sinking in after the intervention, showing the reduction in pressure. All the children were improved in general health and became less apathetic. Among the cases reported in detail was that of a boy of 10, whose head measured 65 cm.; improvement has been progressive during the year since the operation. The results attained to date confirm the advantage of this continuous drainage by puncture of the corpus callosum in every case of hydrocephalus, even in infants, rebellious to internal measures and not benefited by puncture of the ventricle and lumbar puncture.

89. **Localization of Motor Aphasia.**—Monakow concludes this long review of recent research on this subject and clinical experience with the statement that our present means of research are unable to determine the exact connection between the Broca localization, and the remainder of the cortex. There is evidently a comprehensive and complicated center for speech, or rather an area of excitation, both synchronous and successive excitation, of the foci aggregate.

91. See Berlin Letter, Oct. 2, 1909, p. 1112.

92. **Faradization of the Bladder in Treatment of Ataxia in Tabes.**—Herzog applied the induced current directly to the urethra by introducing an electrode about 1 cm. deep into the urethra, with a large electrode on the lumbar region of the spinal cord, passing the current for about three minutes. The measure was applied for cystitis with recurring pyelitis in a patient with tabetic ataxia. From the first sitting the patient noticed that not only the bladder trouble, but his gait was improved, and after twenty applications he was able to return to military service. The ataxia is now so slight that it does not attract lay attention. In 3 other cases similar faradization was equally successful in 2, and with satisfactory results in the other. There was no possibility of influence from suggestion in 2 of the cases. He ascribes the effect to the powerful stimulus from the periphery by way of the intact sensory tracts from the bladder, so he calls the method "faradization of the bladder." He cites Hamilton's recently published success from irrigation of the bladder in tabes, the effect of which is probably by the same mechanism as from the electric treatment.

Deutsche Zeitschrift für Chirurgie, Leipsic

September, CI, Nos. 1-2, pp. 1-204

96 *Operative Treatment in 30 Cases of Tuberculosis of the Kidney. (Zur Nierenchirurgie.) H. Doering.

103 Subcutaneous Prolapse of the Bowel. (Zur Lehre vom subkutanen Intestinalprolaps.) Esau.

96. **Tuberculosis of the Kidney.**—Doering reports the experiences at Braun's clinic at Göttingen with 30 cases of tuberculosis of the kidneys, all but 10 in women. In 19 cases the kidneys were the only site of the tuberculosis. Heredity seemed evident in 9 cases. Pain was the first sign of trouble in all but 2 cases, in which no pain was experienced at any time; fever was observed in the majority, but the kidney was enlarged in only 6 cases. In 25 cases an operation was performed, and 19 of the 20 patients who survived the operation have been recently examined; 4 succumbed to tuberculosis in other organs, but 16, 80 per cent., are in good health from one to eleven years since. He compares his primary mortality with that of others in a compilation of 642 cases. Only 4 of his patients with combined tuberculosis were permanently cured; besides the kidney process, one had a tuberculous bone lesion, the others an apical or cutaneous lesion. He summarizes the details of the entire series.

97. **Dislocation of the Entire Upper Jaw.**—In a horseback accident the upper jaw was separated from the base of the skull, but Thöle succeeded in restoring it to place by means of an appliance exerting pressure by a band passing around an upright rod at the back of the neck, worn for three weeks, and followed by a dental appliance. By the end of six weeks articulation was apparently normal once more.

100. **The Mechanism of the Anal Sphincters.**—Matti's attention was called to this subject by partial incontinence in 3 cases of destruction of some of the muscles, interrupting the continuity of the external sphincter, without disturbance in the innervation. The patients all complained of diarrhea; it was due solely to mechanical insufficiency, although ascribed erroneously to recurring intestinal catarrh and long treated as such in vain. The anus seemed to be intact. The partial defect was in the internal sphincter. Fifty pages are devoted to the description and discussion of his experimental research on the subject, all confirming the functional dependence between the internal and external sphincters and the importance of respecting the sphincters in operating on the rectum. The internal sphincter shares in the peristalsis, and its function in closing the orifice is dependent on mechanical stimulation from the external sphincter muscle.

102. **Trephining in Fracture of the Base of the Skull.**—Luxembourg reports the details of 5 cases in which trephining was done for symptoms of pressure on the brain after fracture of the base of the skull. Clots were found in each case between the dura and the skull, fully explaining the symptoms. The improvement at once or some time after was striking; consciousness returned, the headache subsided partially or entirely and the paralysis was much improved.

106. **Serodiagnosis from Clinical Standpoint.**—Kraus remarks that serodiagnosis not only reveals the identity of the disease-germ, but is an index of the reacting powers of the organism. The defensive reactions are both cellular and humoral, and they are by no means restricted to infections, but have a much broader field. Only part of the antitoxins produced serves for the defense of the organism; a certain proportion evidently becomes the source of further disturbances. He adds that there are probably still other kinds of immunity of which we are ignorant, and it is also probable that cellular immunization plays a far more comprehensive part in clinical pathology than our experimental immunity research has yet revealed. He declares that there is not a single absolutely specific reaction; each biologic reaction is only relatively specific, dependent on the reacting organism, its reaction products and the quantity of antigen available or used for the reaction. He presents the subject classified under various headings and the problems it is opening up before us. In syphilis, for example, it is important to determine whether the Wassermann test is constantly positive in every case of unmistakable syphilis and every return after a quiescent period; whether mercurial treatment constantly transforms a positive into a negative

77. **Operative Treatment of Puerperal Peritonitis and Phlebitis.**—Leopold has previously reported 16 cases of acute puerperal peritonitis in which prompt operation saved twelve of the women, and 2 cases of thrombophlebitis in which one of the patients was saved by ligation of the ovarian veins, the third day after the first chills. He here reports another case of acute peritonitis in which the patient was saved by suturing a ruptured point in the small intestine, the day before delivery. The case confirms the advantages of laparotomy for peritonitis if not more than 2 days old, while the resistance is still good and before the intoxication is too severe. In 2 other cases, purulent thrombophlebitis after delivery was treated by ligation of the ovarian veins, but in both the intervention came too late. In one the source of the pyemia was evidently the suppurated site of the placenta, and early panhysterectomy might possibly have saved the patient. In the second case gonococci had evidently penetrated from the vagina into the veins of the paravaginal tissue, with inflammation of the veins in the right groin and secondary thrombosis of the iliac veins and vena cava. The mistake was made that the vein in the groin was not incised and evacuated when its swollen condition first attracted attention, the fifth or sixth day. The reliance on expectant treatment proved vain. When puerperal thrombosis is accompanied by a rising temperature or a pulse curve which slowly subsides again, the prognosis is favorable, but not when there are remittent high fever and chills. This indicates always some localized pus focus. If the pus cannot escape outward, or if it is in an ovarian or iliac vein, it empties into the vein above, and this must be prevented at all hazards; this is possible only by early search for and evacuation of the pus focus. The thrombi may pass into the vena cava early and the germs penetrate the vessel wall, the resulting inflammatory edema soldering veins and arteries together. In the last case this was responsible for his mistaking the hypogastric artery for the thrombosed vein. The attempt to ligate the iliac vein proved impossible, as it could not be separated from the artery. The lesson from his 21 cases, he says, is to operate and operate early, but never too late.

78. **Tuberculin Treatment of Pulmonary Tuberculosis.**—Pel read this article at the recent international medical congress, concluding his remarks with the statement that tuberculin is still in the period of trial. He has been unable to acquire much enthusiasm for it. There are so many unaccountable by-effects, such as headache, fever, insomnia, rheumatoid pains, loss of appetite and weight, acceleration of the pulse and general depression, while acute exacerbations or complications of the tuberculous process may be encountered, as also an individual hypersusceptibility to tuberculin. The course of treatment is so long, so complicated, the indications are so restricted and there are so many contraindications, that he declares that failure to institute tuberculin treatment is not a sin of omission, for the present. The clinics, hospitals and sanatoriums should make a point of comparative and critical study of tuberculin treatment to place it on a solid basis.

83. **Early Sign of Arteriosclerosis.**—Engel calls attention to the differential importance of variations in the blood pressure in different vascular areas. The systolic blood pressure is the expression of the effort of the heart plus the elasticity of the vessels. If there is mechanical obstruction in the vessels, the blood pressure in the area will be proportionately reduced. A circumscribed arteriosclerotic process causes the blood pressure in the region to become much lower than in the area on the other side. The variation is slight, not more than from 5 to 15 mm. mercury, and it may not be evident to the finger, but it can be readily measured with the tonometer. The difference has diagnostic importance only when it is found constant on repeated examination. Consequently, if a constant difference of 5 mm. is found in the pressure in the right and left arm, for instance, this is an essential aid for the diagnosis of arteriosclerosis. This finding is also important for differentiating primary nephritis from arteriosclerosis. In nephritis the cause of the increased blood pressure acts uniformly throughout the body, and local disturbances do not occur in single vascular areas, as in case of arteriosclerotic lesions in the walls of the vessels.

87. **Scrofula.**—Escherich remarks that the cutaneous Pirquet tuberculin reaction and scrofulous skin lesions—scrofulides—are influenced alike by injections of tuberculin. This cutaneous test has shown the connection between the non-bacillary manifestations of scrofula and tuberculosis. The true cause of scrofulous changes in the skin is the hypersensitiveness of the skin and mucosæ resulting from the presence of the antibody, that is, the tuberculous "allergy." The difference between the toxic and the bacillary symptoms of tuberculosis has long been recognized, and is a reason for maintaining the term "scrofula" or "scrofulide" to express the tuberculo-toxic changes in the skin. The term "scrofula" he would retain for those cases of tuberculosis in which the focus is latent and there are merely the lesions known as "scrofulides." If signs of a manifest bacillary focus are present also, he would call this "scrofulo-tuberculosis." Pure scrofula is the most harmless form of tuberculosis in children. A complete cure is the rule, and it confers relative protection against later infection. This also applies to some extent to scrofulo-tuberculosis. It may be obstinate, but it is generally benign. The discovery of the typical scrofulides is thus important for both prognosis and treatment. He discusses the connection between the status lymphaticus and scrofula, accepting some congenital constitutional anomaly, manifested by the former, as the basis for the development of the scrofulous symptoms in the course of tuberculosis. The article, which was presented as an address at the recent international medical congress, emphasized the importance of tuberculin in treatment of scrofula, to supplement the usual measures.

88. **Treatment of Hydrocephalus by Puncture of the Corpus Callosum.**—Bramann has applied this method of treatment in 22 cases, including 8 of hydrocephalus. He aims to relieve the pressure on the brain by perforation of the corpus callosum to establish a broad communication between the fluid in the ventricle and the subdural space of the brain and spinal cord. He assumes that the active flow of the fluid between the ventricle and subdural space will prevent the opening from growing up. For children it is unnecessary to trephine, as a curved cannula can be inserted through a small incision in the dura, close to the sinus, after incising the skin about the middle of the anterior fontanelle, 1 cm. to the right of the median *line*. The cannula is then pushed in between the wall of the sinus

and the surface of the brain toward the median line until the tip of the cannula reaches the falx and glides along this to the corpus callosum, through which it is pushed. After allowing escape of fluid, which is generally under high pressure, the cannula is worked to and fro until the hole is sufficiently enlarged to ensure its remaining open; then the cannula is removed. In his 8 cases of hydrocephalus the improvement was marked, the fontanelle no longer protuding, but sinking in after the intervention, showing the reduction in pressure. All the children were improved in general health and became less apathetic. Among the cases reported in detail was that of a boy of 10, whose head measured 65 cm.; improvement has been progressive during the year since the operation. The results attained to date confirm the advantage of this continuous drainage by puncture of the corpus callosum in every case of hydrocephalus, even in infants, rebellious to internal measures and not benefited by puncture of the ventricle and lumbar puncture.

89. **Localization of Motor Aphasia.**—Monakow concludes this long review of recent research on this subject and clinical experience with the statement that our present means of research are unable to determine the exact connection between the Broca localization, and the remainder of the cortex. There is evidently a comprehensive and complicated center for speech, or rather an area of excitation, both synchronous and successive excitation, of the foci aggregate.

91. See Berlin Letter, Oct. 2, 1909, p. 1112.

92. **Faradization of the Bladder in Treatment of Ataxia in Tabes.**—Herzog applied the induced current directly to the urethra by introducing an electrode about 1 cm. deep into the urethra, with a large electrode on the lumbar region of the spinal cord, passing the current for about three minutes. The measure was applied for cystitis with recurring pyelitis in a patient with tabetic ataxia. From the first sitting the patient noticed that not only the bladder trouble, but his gait was improved, and after twenty applications he was able to return to military service. The ataxia is now so slight that it does not attract lay attention. In 3 other cases similar faradization was equally successful in 2, and with satisfactory results in the other. There was no possibility of influence from suggestion in 2 of the cases. He ascribes the effect to the powerful stimulus from the periphery by way of the intact sensory tracts from the bladder, so he calls the method "faradization of the bladder." He cites Hamilton's recently published success from irrigation of the bladder in tabes, the effect of which is probably by the same mechanism as from the electric treatment.

Deutsche Zeitschrift für Chirurgie, Leipsic

September, CI, Nos. 1-2, pp. 1-204

96 *Operative Treatment in 30 Cases of Tuberculosis of the Kidney. (Zur Nierenchirurgie.) H. Doering.

102 *Trephining for Fracture of Base of Skull. (Zur Frage der Trepanation bei Schädelbasisbrüchen.) H. Luxembourg.
103 Subcutaneous Prolapse of the Bowel. (Zur Lehre vom subkutanen Intestinalprolaps.) Esau.

96. **Tuberculosis of the Kidney.**—Doering reports the experiences at Braun's clinic at Göttingen with 30 cases of tuberculosis of the kidneys, all but 10 in women. In 19 cases the kidneys were the only site of the tuberculosis. Heredity seemed evident in 9 cases. Pain was the first sign of trouble in all but 2 cases, in which no pain was experienced at any time; fever was observed in the majority, but the kidney was enlarged in only 6 cases. In 25 cases an operation was performed, and 19 of the 20 patients who survived the operation have been recently examined; 4 succumbed to tuberculosis in other organs, but 16, 80 per cent., are in good health from one to eleven years since. He compares his primary mortality with that of others in a compilation of 642 cases. Only 4 of his patients with combined tuberculosis were permanently cured; besides the kidney process, one had a tuberculous bone lesion, the others an apical or cutaneous lesion. He summarizes the details of the entire series.

97. **Dislocation of the Entire Upper Jaw.**—In a horseback accident the upper jaw was separated from the base of the skull, but Thöle succeeded in restoring it to place by means of an appliance exerting pressure by a band passing around an upright rod at the back of the neck, worn for three weeks, and followed by a dental appliance. By the end of six weeks articulation was apparently normal once more.

100. **The Mechanism of the Anal Sphincters.**—Matti's attention was called to this subject by partial incontinence in 3 cases of destruction of some of the muscles, interrupting the continuity of the external sphincter, without disturbance in the innervation. The patients all complained of diarrhea: it was due solely to mechanical insufficiency, although ascribed erroneously to recurring intestinal catarrh and long treated as such in vain. The anus seemed to be intact. The partial defect was in the internal sphincter. Fifty pages are devoted to the description and discussion of his experimental research on the subject, all confirming the functional dependence between the internal and external sphincters and the importance of respecting the sphincters in operating on the rectum. The internal sphincter shares in the peristalsis, and its function in closing the orifice is dependent on mechanical stimulation from the external sphincter muscle.

102. **Trephining in Fracture of the Base of the Skull.**—Luxembourg reports the details of 5 cases in which trephining was done for symptoms of pressure on the brain after fracture of the base of the skull. Clots were found in each case between the dura and the skull, fully explaining the symptoms. The improvement at once or some time after was striking; consciousness returned, the headache subsided partially or entirely and the paralysis was much improved.

106. **Serodiagnosis from Clinical Standpoint.**—Kraus remarks that serodiagnosis not only reveals the identity of the disease-germ, but is an index of the reacting powers of the organism. The defensive reactions are both cellular and humoral, and they are by no means restricted to infections, but have a much broader field. Only part of the antitoxins produced serves for the defense of the organism; a certain proportion evidently becomes the source of further disturbances. He adds that there are probably still other kinds of immunity of which we are ignorant, and it is also probable that cellular immunization plays a far more comprehensive part in clinical pathology than our experimental immunity research has yet revealed. He declares that there is not a single absolutely specific reaction; each biologic reaction is only relatively specific, dependent on the reacting organism, its reaction products and the quantity of antigen available or used for the reaction. He presents the subject classified under various headings and the problems it is opening up before us. In syphilis, for example, it is important to determine whether the Wassermann test is constantly positive in every case of unmistakable syphilis and every return after a quiescent period; whether mercurial treatment constantly transforms a positive into a negative

response; whether women apparently healthy but giving a positive response bear syphilitic children; whether persons giving a positive reaction are able to infect others, have relapses and develop tabes, paralysis or aortitis, and, finally, whether new primary infection is possible in persons giving a positive response. At the same time the investigator must bear in mind the analogy to other infectious diseases; the survival of the antibodies after recovery from the disease; the occurrence of positive reaction many years after the last manifestations; the fact that men giving a positive reaction are yet able to marry and rear healthy children and the wife remain healthy; fluctuations in the reaction; the possible development of paralysis notwithstanding apparently effectual mercurial treatment, and the occurrence of a positive response even in the stage of paralysis, although the latter cannot be cured by mercury. It is possible, he continues, that the Wassermann test may prove a guide for an individualizing biologic mercurial treatment and aid in the prognosis, as positive findings indicate that recovery is not complete. He regards it as established that progress will be realized by occasional repetition of the test and institution of renewed treatment in case of positive findings, hoping that in this way it may be possible to ward off paralysis and tabes. He has not found the cutaneous tuberculin reaction of much value for adults, but considers it extremely important for children. The tuberculin reactions depend on the force of the stimulus, the excitability and capacity for reacting of the cells—all of which are variable factors, and all should be borne in mind in estimating the response to the test. In conclusion, he remarks that the internists and the general practitioners pay altogether too little heed to the possibilities of serodiagnosis at present. There is grave danger that by leaving to special institutions the exercise of the different diagnostic and therapeutic measures, they may lose their own birthright, and that diseases, and not the diseased individuals, will get the treatment. There is also danger for the general practitioner striving to learn the technic of some special diagnostic method, such as the Wassermann test, and taking a special "lightning course" in the technic. While specializing in this single reaction he leaves out of account altogether the other achievements of immunity research, and thus gets a one-sided view of the subject.

107. **Operative Treatment of Epilepsy.**—Krause has operated in 12 cases of general epilepsy since 1906, and one of his patients, a man of 31, was so improved that he has been able to manage his large factory for three and a half years. Before the operation he had up to three seizures a day, but since they recur only every fourth or sixth week. Another patient, a man of 21, has had no seizures during the year and a half since the operation. No appreciable benefit was observed in the other cases. Cooperation between neurologists and surgeons will certainly lead to progress in the operative treatment of epilepsy, such as has already been realized in other operative affections of the spinal cord and brain.

109. **Differentiation of Tricuspid Insufficiency.**—Hering remarks that increased knowledge has robbed us of what was supposed to be a certain sign of tricuspid insufficiency, namely, the jugular-ventricle pulse (*Kammervenenpuls*). This is as much as to say that we have at present no means of diagnosing tricuspid insufficiency. At the same time, in a certain number of cases, we are in a position to exclude tricuspid insufficiency, notwithstanding the existence of the jugular-ventricle pulse. These are the cases in which the jugular pulse is so weak that it is scarcely recognized as such, but the pulse is of the permanently irregular type, there are no signs of stasis and there may be absolutely no heart murmur. These features of the case exclude tricuspid insufficiency. Only when the jugular-ventricle pulse is pronounced should it be suspected.

112. **Operations for Goiter.**—Schloffer has been able to learn the late results in 235 of 450 patients on whom he has operated for goiter during the last six years, and expects to hear from others. In 199 cases the patients report most gratifying results from the operative treatment, but in 28 the tumor has recurred, causing some disturbance, and in 32 without disturbances. Eight patients say the operation gave no relief. The operative mortality in the cases without suffocation was 1.6 per cent., but 5 of the 130 patients who had typical attacks of suffocation succumbed.

114. **Simplified Technic for Determination of the Gastric Acidity.**—Müller gives a colored chart to serve as the color scale for the test, the eight separate tints ranging from clear yellow, in the cases with total absence of acidity, through intermediate orange tints to a reddish violet in the cases with high acidity. He never found more than 1 per thousand acidity in his tests. The stain is a cold saturated alcoholic solution of the stain tropæolin-00, and 0.1 c.c. of the solution is added to 5 c.c. of gastric juice, when at once the mixture is ready for comparison with the color scale given on a fly-leaf for ready reference. He adds the tabulated details of 24 cases in which the findings with this simple test were compared with the more complicated usual tests, the agreement between them being almost complete. This test reveals the proportion of hydrogen ions present, and thus is a more exact index of the actual acidity than the titration methods. The tint is always the same, he says, for fluids containing the same number of these ions.

Monatsschrift für Geburtshülfe und Gynäkologie, Berlin

September, XXX, No. 3, pp. 261-416

116 *Appendicitis and Affections of the Adnexa. (Appendicitis und Erkrankungen der Adnexa uteri.) A. v. Rosthorn.

119 *The Levator Ani in Respect to Recurrence After Operations for Prolapse. (Bedeutung des Levatorspaltes für die Rezidivprognose der Prolapsoperation.) Adolph.

116. **Appendicitis and Affections of the Adnexa.**—This last communication from the pen of v. Rosthorn discusses the connection between disturbances in the appendix and adnexa and the differentiating points. He gives a number of ilustrative examples; and appeals for further study of: 1. The frequency of appendicitis in women. 2. The causal relation between affections of the appendix and of the female genitalia. 3. Differentiation. Disturbances in menstruation and painful menstruation should not always be referred to pathologic changes in the genital sphere, especially in virgins; pelvic symptoms and suppuration may be traceable to the appendix. 4. Adhesions connecting the appendix and the pathologic internal genital organs are comparatively rare. When they do occur pronounced symptoms may be absent, but they favor the spread of infectious processes from one to the other. 5. The development of appendicitis, chronic from the start, must be accepted. Efforts to define this vague clinical picture are in order to differentiate it from the numerous similar conditions from other causes. 6. The appendix should be examined whenever the abdomen is opened for any cause, but its prophylactic removal requires further research on the physiologic value of the appendix and of the disturbances from lack of its functioning; of the histologic changes to determine whether they are of pathologic nature or not; of the proportion of cases of appendicitis in persons who have been operated on for other pelvic affections; the proportion of permanent cures of the genital affections after appendicectomy and the causes of the numerous failures. 7. The slightest suspicion of appendicitis of course turns the scale in favor of the abdominal route for operating on the pelvic organs. The acceptance of the principle of always removing the appendix brings with it the constant choice of the abdominal route for all operations on the adnexa. 8. There are no sufficient data at present to form any judgment in regard to the frequency of acute appendicitis as a cause of abortion and of postappendicitic changes as a cause of habitual abortion, and the importance of appendicitis as a factor in sterility.

112. **Operations for Goiter.**—Schloffer has been able to learn **Ani Muscles.**—Adolph has been able to examine recently 152 women of the 186 operated on for prolapse between 1904 and 1907, seeking to determine the influence of the gap between the levator ani muscles as a factor in the prolapse. Childbirth stretches these muscles so far apart that the solidity of the floor of the pelvis is much impaired, and his research has shown that this insufficiency of the genital hiatus is frequently overlooked or neglected. It is sometimes impossible to remedy

it, and he asks whether tubal sterilization ought not to be proposed for women with total insufficiency corrected by an operation but sure to return under the stress of another delivery. In his experience the cleft was found nearly normal in 66 cases, moderately enlarged in 23, and extremely enlarged in all the others. Classification of the prolapses shows that the size and severity parallel the width of the cleft of the levator ani muscles, and the end results of the operation for the prolapse show this parallel course still more pronounced. The size of the uterus is also important, as total prolapse more readily occurs with a small hiatus when the uterus is small. Sometimes large prolapse of the vagina with a much enlarged cervix simulates total prolapse, but in reality this is not the case unless the uterus is small. When it is large it does not descend so readily, but when the hiatus is very wide the size of the uterus is not of much moment for the amount of prolapse. It is therefore evident that by determining the width of the gap between the levator ani muscles it is possible to foretell the outcome of an operation for prolapse. Even hysterectomy does not ensure against recurrence of the prolapse if the hiatus is left unduly gaping. If it cannot be closed, the aim should be to hold up the uterus in some way and to strengthen the levator muscles by exercise. The recent anatomic research in this line explains the success realized by T. Brandt in the cure of prolapse by his gymnastic exercises, which was at first regarded so skeptically. All this applies especially to primiparæ, as the conditions preparing the way for prolapse are created almost invariably at the first child-birth. Forcible delivery is especially liable to enlarge this hiatus and thus deprive the genital organs of the necessary support from the juxtaposition of the levator ani muscles. In about half of the cases of the widest hiatus the child had been delivered with forceps. In 80 per cent. of his cases the women had remained in bed until the eighth day after delivery.

126 Determination of Coagulating Time of Blood. (Neue Methode zur Bestimmung der Gerinnungszeit des Blutes.) W. Riebes.

120. **Inheritance of Syphilis.**—Baisch reports from Döderlein's clinic for women at Munich the results of his research seeking to define the serologic and bacteriologic laws governing the transmission of syphilis to the offspring. In about 80 per cent. of the cases of maceration of the fetus, syphilis must be incriminated, but in the remainder nephritis in the mother or possibly tuberculosis, malformation of the fetus or entanglement in the umbilical cord is responsible for the premature death of the fetus. Typical habitual abortion in the first four months of pregnancy does not belong to the symptomatology of syphilis. The mothers of syphilitic children are probably all infected with syphilis, but fully 75 per cent. of such mothers in his experience presented no certain signs of syphilis and the Wassermann test is frequently negative. Colle's and Profeta's laws are explained by the fact that new infection is impossible, as infection is already installed. The best prospects for therapeutic success are in energetic treatment of the mothers before and during the pregnancy.

123. **Fever After Injection of Salt in Infants.**—Friberger reports experiences with 74 infants, averaging three months old, injected subcutaneously with 10, 30 or 60 c.c. of physiologic salt solution. A rise of temperature was observed in only 28, and although the curve was typical, yet there did not seem to be any regularity in the febrile response. As a rule, the response was most regular in the infants with intestinal disturbances.

138 Femoral Hernia (Radikal-Operationen von Schenkelhernien.) J. Fabricius.

139 *Diseases of the Esophagus. (Erkrankungen der Speiseröhre.) R. Kaufmann and R. Kienböck. Commenced in No. 36.

136. **Hemolytic Reaction in the Serum with Cancer.**—Kelling's statements in regard to the specific reaction in the serum of patients with cancer have been summarized in THE JOURNAL. He here tabulates the findings in a series of 100 patients tested for the hemolytic reaction to both human and fowl blood corpuscles. Also in a series of 50 tested with less concentrated suspensions. The results confirm the differential importance of the isolysin tests for the diagnosis of cancer. His experience includes also a series of 600 cases in which the test was applied similarly to the first series of 600 reported in 1907 and with similar findings. In conclusion he tabulates the parallel findings with the hemolytic and the complement-binding tests in 200 cases. No reaction was apparent in 96 cases of ulcer, neurosis, gastritis, gall-stones, gastrointestinal catarrh or anemia, while one or the other or both were positive in all but 4 of the 78 cases of carcinoma, all but 2 in the digestive tract.

139. **Affections of the Esophagus.**—In this communication from Kienböck's radiologic institute at Vienna, 13 cases of an affection of the esophagus are reported with the autopsy findings in some and the lessons learned therefrom. In some cases a primary diverticulum induced secondarily spastic closure of the cardia. In others a large diverticulum existed but the periodical recurrence of the disturbances in swallowing showed that the diverticulum was not directly responsible for them. It is evident that the decomposition of the food lodged in the diverticulum irritated the mucosa and thus was the indirect cause of closure of the cardia. In some cases of idiopathic dilatation of the esophagus the rinsing out of the esophagus did not banish all the disturbances, especially the spasm, until it was supplemented by administration of atropin. When the rinsing out the esophagus cures in such cases, the vagus is manifestly not responsible for the disturbances; a local pathologic condition of the mucosa of the esophagus is inducing the spasm. On the other hand, when there are signs of a neuritis or neurosis of the vagus, or compression or atrophy of this nerve, this alone suffices to explain the spasm, contraction or paralysis interfering with the act of swallowing, and atropin will benefit and possibly cure.

140 *Femoral Hernia. (Zur Radikaloperation des Schenkelbruches.) H. Hans.
141 Technic for Gastroenterostomy. R. Lenzmann.
142 *Resection of Middle Duodenum. W. Kausch.

140. **Radical Operation of Large Femoral Hernia.**—Hans gives an illustrated description of a method of wire fixation which has proved extremely useful for very large femoral hernias. Poupart's ligament is changed from a flat to a vertical plane and Gimbernat's ligament is strengthened and spread by two stout silver wires, forming a triangle, which embraces the bone and forms a solid support, the ends being sunk in the bone. This technic has the advantages of the Roux method of nailing the ligament to the pubis with a silver double pointed nail, while it does not have the drawback of this, namely, that the nail works loose in time.

142. **Resection of Middle Duodenum.**—Kausch has been much pleased with the results of operating on the duodenum in two sittings, as in a case of cancer of the papilla reported. The first step is merely an anterior cholecystotomy with enteroanastomosis; this relieves the patient and frees him from jaundice. Two months later the radical operation follows, mobilization of the duodenum, posterior gastroenterostomy and resection of the duodenum, first closing the pylorus, then ligating the common bile duct, then cutting the pancreas, including its duct, but without ligation of the latter, then severing the duodenum. The oral stump of the duodenum is then drawn over the cut surface of the pancreas like a cap and sutured there. The ligated end of the bile duct is also drawn into the lumen. By this means the pancreas secretion and discharge from the cut surface all flow into the intestine, and the method permits extensive resection of duodenum, pancreas and bile duct. In the case reported, the patient stood the four-hour operation well and made a smooth recovery, although stomach content, bile and pancreatic juice escaped from the drain for about seventeen days.

148 Displacement of Apex Beat with Mitral Defect. (Impulso da cardiaco invertito in un caso di doppio vizio mitralico.) U. Deganello.

146. **Vomiting of Pregnancy and Suprarenal Treatment.**—Rebaudi writes from Bossi's clinic at Genoa to call attention to the remarkable effect of a few cubic centimeters of a solution of the juice from the capsule of the suprarenals in promptly arresting previously uncontrollable vomiting. The patient was a young woman at the third month of her second pregnancy dangerously debilitated from the almost incessant vomiting. All other treatment was suspended except the nutrient enemas, and 10 drops of 1 to 1,000 adrenalin solution were given morning and night, at first in an enema of 150 gm. water with 20 drops of laudanum, after three days in ice water by the mouth. The vomiting ceased by the second day and by the third the patient was able to retain a little food. On the eleventh day the dose was reduced to 10 drops a day, and this was kept up for nine more days. Toward the end of the pregnancy there was a recurrence of tendency to nausea and 10 drops of the adrenalin solution were given for five days, during which the tendency subsided and a well-developed child was delivered at term and is now growing normally.

151 *Malta Fever. (Febbri e febbricole setticemiche da micrococco di Bruce. VIII.) G. Rummo.
152 *Reaction to Differentiate Exudation from Transudate. (Nuova reazione per differenziare gli essudati dai transudati.) S. Gangi.

151. **Malta Fever.**—Rummo describes the characteristics of this disease, mentioning that the incubation may vary from three to fifteen days or more, while the disease may last for a few weeks to several months or even years, though early complete recovery is the rule. There is no special type of fever, and the disease can be differentiated from paratyphoid or an atypical typhoid, he asserts, only by the seroreaction. The micrococcus has been found in the blood in 80 per cent. of the cases.

152. **Differentiation Between Exudates and Transudates.**—Gangi describes a test which he has found simple and reliable for this purpose. It is based on Heller's test for albumin in the urine: In a test tube containing 2 or 3 c.c. of hydrochloric acid, 3 or 4 c.c. of the fluid to be examined is allowed to flow down the side. In the presence of an exudate a white cloud appears and forms a ring at the zone of contact between the two liquids. From the upper surface of this ring white clouds gather and rise, similar to the puff of smoke that rises when a lighted cigarette is struck lightly. These clouds gather to form a zone at first at the surface but then gradually sinking somewhat below the surface of the fluid in the test-tube, with a zone of limpid fluid above and below them down to the white ring. The ring gradually increases in width and density and finally clings to the walls of the test-tube and bubbles of gas are observed. With a transudate, on the other hand, the ring at the zone of contact is small and narrow and the fluid above persists limpid throughout, or there may be no ring; after a period of turbidity the fluid mixes with the acid below and forms a homogeneous turbid brownish fluid. He discusses the mechanism of this reaction, suggesting that the presence of proteids does not explain it entirely and that certain products of bacterial metabolism may also be involved.

BACTERIAL EXAMINATION OF THE STOOLS IN SUSPECTED CANCER OF THE STOMACH *

PHILIP KING BROWN, M.D.
SAN FRANCISCO

It is surprising that the facts presented by Rudolf Schmidt from Neusser's clinic in 1906 regarding the presence of the Boas-Oppler bacilli in the stools in cancer of the stomach has attracted so little attention in view both of Schmidt's well-known standing and the expressed conviction of Neusser as to the significance of the finding. Schmidt showed the following fact: The bacterial examination of the stools by Gram's stain under normal conditions gave a picture of very few organisms, the Gram-negative colon group vastly outnumbering any Gram-positive organisms. The normal stool Schmidt called Gram-negative. A stool that with Gram's method showed uniform-sized bacilli far outnumbering all other organisms he regarded as Gram-positive. Occasionally a stool was found in which Gram-staining organisms in great varieties outnumbered other organisms; these organisms were chiefly cocci and non-uniform bacilli which he differentiated in a manner to be referred to later. They are not Gram-positive in the sense that the predominating organism is a well-staining uniform bacillus. Schmidt takes the ground that Boas-Oppler bacilli are vastly more easily found in the stools than in the gastric contents, which is quite true, and he believes that if the morphologic characteristics of the Boas-Oppler bacilli are determined in differentiating them, their relation to cancer becomes of greater significance. He has stated, as have a great many other observers who have followed the matter carefully, that many organisms have been mistaken for the Boas-Oppler bacilli. This has served to put the relation of the Boas-Oppler organism to cancer in considerable doubt. While not contending that the occurrence of the organism is characteristic of cancer, Schmidt points out how easily the organism is mistaken for certain other bacilli. Every one who has studied this question at all will admit at once that our diagnosis of Boas-Oppler bacilli is made on very insufficient grounds, when one considers the care that Schmidt has exercised in differentiating them. Certainly hereafter all the deductions about the relation of the organism to cancer must be made on an absolute determination of what is the Boas-Oppler bacillus.

In a study of a large series of cases from Neusser's clinic and from the subsequent reports by a few other observers, the following deductions may be made:

1. A typical Gram-positive stool may occur in:
   Primary cancer of stomach.
   Ulcer of stomach (Elliott. Not confirmed at operation or autopsy).
   Typhoid (Neusser).
   Cancer of the uterus with emaciation and cachexia (Neusser).
2. "Gram-negative stools exclude cancer of the stomach" (Neusser).

Elliott, however, found a secondary cancer of the splenic region with a Gram-negative stool, and one other gastric cancer with uremia and excessive vomiting, also with a Gram-negative stool.

My own findings thus far in a series of cases of cancer of the stomach in which the diagnosis was confirmed at operation or autopsy have failed to show any cases in which the stool was other than Gram-positive, and in no case of acute or chronic ulcer has the stool been other than Gram-negative, on repeated examinations.

The most interest, however, centers about four cases in which a diagnosis of gastric ulcer was made on account of the clinical history, pain, lack of cachexia and the presence of free hydrochloric acid in the stomach. Although the bacteriologic examination of the stool had been made in each case, its importance was not held to be sufficient to warrant its being weighed in the evidence. In each case an operation was performed and the diagnosis made clinically as follows:

CASE 1.—Clinical diagnosis, ulcer of stomach at pylorus. Operation, extirpation of pylorus. Microscopic examination: diagnosis, malignant degeneration of ulcer in the pyloric opening.

CASE 2.—Clinical diagnosis, ulcer of stomach. Operation, gastroenterostomy. Death from hemorrhage. Diagnosis at autopsy, malignant degeneration of ulcer of the lesser curvature near pylorus.

CASE 3.—Clinical diagnosis of multiple ulcer with uncontrollable hemorrhage. Operation, gastroenterostomy; revealed extensive secondary cancer, a primary tumor in the gall- bladder, stomach wall involved in several places. Diagnosis confirmed at autopsy.

CASE 4.—Clinical diagnosis of ulcer of the pylorus. Operation, pylorectomy. Several areas of cancerous degeneration in large ulcer at pylorus.

I have not entered into detail in these cases as to the ground for clinical diagnosis of ulcer of the stomach. I believe in each case that such a diagnosis was entirely justifiable in the light of the symptoms. The significant point of it is the great importance that was apparently attached to the one symptom that was not weighed with the others. Personally, I should continue the bacteriologic examination of the stools in doubtful cases with very much more interest than before, for not only is the early diagnosis of cancer a matter of the utmost importance, but one can not fail to be impressed with the extraordinary reports of the Mayos as to the frequency with which cancerous degeneration of ulcer occurs.

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

Schmidt's technic is as follows:

Make thin smears.

Dry and fix five minutes in methyl alcohol (thus dissolving also fat).

Stain five minutes in anilin-oil-gentian-violet; wash.

Iodin-potassium-iodid solution till deep purple; wash.

Decolorize in 95 per cent. alcohol till nearly colorless; wash.

Stain in weak aqueous solution of fuchsin; wash; dry; mount.

In considering the difficulties in recognizing the Boas-Oppler bacilli, Schmidt calls attention to the following types:

1. Lactic acid bacillus type; these organisms are thinner than the colon group, vary greatly in length, show no spore formation, are non-motile, show areas of Gram-negative stain, stain yellow with Lugol solution and show granules in the protoplasm. All characteristics are identical with the bacilli found in the coffee-ground vomitus of cancer of the stomach.
2. Pseudo-colon group; these have the same morphology as the Gram-negative colon group, except that they are Gram-positive and non-cultivable. They occur in catarrh of the bowel, especially with acid stools.
3. Gram-positive bacilli, thicker than the Boas-Oppler and occurring in long chains, staining blue with Lugol solution, non-cultivable; occurring in chronic catarrh of the lower bowel, especially when atony and flatulence are present.
4. Emerson says that "some passing under this name (i. e., Boas-Oppler), are surely the gas bacillus."
5. It seems probable that the common *bacillus subtilis* is often mistaken for the Boas-Oppler, especially in stained specimens of stomach contents.

350 Post Street.

ABSTRACT OF DISCUSSION

Dr. Herman B. Allyn, Philadelphia: Do the bacilli which are Gram-positive appear early in the stools in cancer of the stomach?

Dr. Allen A. Jones, Buffalo: Has Dr. Brown found the Oppler-Boas bacilli in the gastric contents in those cases in which the bacilli were Gram-positive in the stools? If so, did the cases prove later to be gastric cancer?

Dr. Anthony Bassler, New York: I have also observed the Boas-Oppler bacilli in the stools in some instances of gastric carcinoma. Recently I have been interested in making slides from the back of the tongue and throat in stomach cases. While in vomiting they are often found in the mouth, lately I saw a case in which there was no vomiting, but the organisms were found in large numbers, probably having been carried up by the eructations that were present.

Dr. Philip King Brown, San Francisco: I found these bacilli in the stools early in cases of cancer. In four cases in particular in which diagnosis of ulcer was considered the most probable one, they were evident. If these bacilli are Gram-positive, they should make one suspicious of cancer of the stomach. I did not look for them in the gastric contents. In the four cases attended with Gram-positive findings, the diagnosis was confirmed finally at autopsy or at operation.

Bacteria in Pasteurized Milk.—M. J. Rosenau, in *Annals of Medical Practice,* states that pasteurized milk must be handled with the same care as raw milk, if not with greater. Pathogenic bacteria grow more readily in milk which has been heated than in raw milk. The germicidal properties of the milk are destroyed by high heating, and finally the surviving bacteria do not have so hard a struggle for existence in the heated milk. It must not be forgotten that pasteurization kills only the major portion of the non-spore-bearing bacteria, and that a large number of micro-organisms remain, and, if permitted to grow and multiply, they may occasionally produce undesirable qualities or perhaps poisonous properties in the milk

---

AMEBIC DYSENTERY *

SIDNEY K. SIMON, A.B., M.D.
Lecturer on Clinical Medicine, Tulane University; Visiting Physician, Touro Infirmary
NEW ORLEANS

Dysentery has been known as an independent malady of widespread and almost universal distribution since the most remote period of time. In the very earliest writings on medicine references may be found to the disease, and the part it has played through the ages, especially in connection with the fatalities of army life, has left an impress on the historical records of nearly every nation. It is only within what might be called modern times, however, that a step has been made toward the closer analysis and classification of the disease. The differentiation of the old-time bloody flux, with its confused clinical picture, into the two clearly defined types identified to-day under the names of amebic and bacillary dysentery, has been the result of investigations entered upon only within the past half-century.

HISTORY

Lambl, in 1859, was in fact the first to offer the suggestion of a possible specific cause for dysentery. In the course of a routine examination of the intestinal mucus of a child who had died of enteritis he ran across an ameboid body, probably a flagellate, which impressed him as a possible factor in the inflammatory process. This observation did not, however, seem to create much comment at the time and no further investigation was made in this direction until 1875, when Loesch was able to identify probably the first true amebæ in the dejecta of a characteristic case of dysentery, originating in St. Petersburg. Eleven years later Kartulis, working in Egypt, always a hotbed of dysentery, reported 150 cases from that country, in all of which he found the ameba. Subsequently he noted the same organism in liver abscesses. Koch had, however, three years before, demonstrated amebæ in sections from an ulcerated bowel, showing a direct causal relationship between the parasite and the intestinal lesion.

In this country the first amebæ discovered were by Osler, in 1890. Shortly afterward, confirmation came from various sources. Within one year Stengel found 3 cases of true amebic dysentery in Philadelphia and Musser 4 from the same city, while Dock was able to report 12 cases of the acute and chronic types from Galveston, the first to be recorded from the far South. The disease has subsequently been found to exist, scattered over many other sections of this country, and, in fact, in nearly all parts of the world sporadic cases crop out occasionally, apparently of purely indigenous origin. Even in such northern latitudes as Germany, England, Japan, or even Russia, there come reports at times of its occurrence; but the disease is essentially a tropical or semitropical one and prevails more extensively in warm climates, in connection usually with a low-lying or poorly drained soil.

In certain regions of the South, including a comparatively large area of our country, conditions are almost ideal for the prevalence of an amebic infection. It is only within very recent years, however, that its occurrence in the South, in wide-spread endemic form, has come to be suspected, and even to-day the question is scarcely regarded by the profession in a light at all befitting its high importance. In spite of the frequent case-reports from Southern observers, the impression has nevertheless seemed to persist in part that the disease is of rare occurrence in the United States and that the relatively few instances which find their way into print might be traced to a previous residence in the tropics. This impression should no longer be allowed to go unchallenged. As far at least as the South is concerned nothing could be falser. The disease, it should be insisted on with the greatest possible emphasis, does find a home ideal for its existence and dissemination in the semitropical environment of the South, is and has been for years widely prevalent there, though unfortunately masked all too frequently under the vague and generalized term of simple chronic diarrhea, or some such indefinite diagnosis.

---

* Read in the Section on Practice of Medicine of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

Of the truth of these facts there can be found testimony sufficiently suggestive in the various scattered case reports of Southern observers, such as Harris from Atlanta, Jelks from Memphis, Wilson from Birmingham, Wasdin from Charleston, Dock from Galveston, Slaughter from Virginia, and many others. As a further contribution to this array of evidence I wish to offer an additional group of 50 cases from New Orleans, which I have been able to collect during the past two years, partly from my own records and partly from those of my colleagues with whom I am associated in the hospitals. These few cases, I need only remark, serve merely an an index to the prevalence of the amebic dysentery in our particular section and do not in any way begin to cover the field. On the contrary, I am convinced that, were the full facts known, as they should be, the number of cases at present unrecognized and overlooked in all parts of the South would be found to foot into the many hundreds. In fact, the tardy recognition accorded this wide-spread amebic infection bears a faint resemblance to the history of the hookworm disease in the South. Before Stiles' epoch-making discovery, thousands of hookworm sufferers, as we now know, dragged out a miserable existence, weighted down in most instances under a false diagnosis.

In part extenuation of this hesitancy and failure in recognition, the extremely variable and capricious symptom picture of amebic dysentery, it is true, makes a purely bedside diagnosis uncertain, and may even tend to disarm an ordinary suspicion of its existence. The term "dysentery" has come to be associated in our minds with such classical symptoms as an outspoken tenesmus, small, frequent and liquid evacuation, containing blood and mucus, all running a more or less rapid and acute course. This clinical picture, however, could scarcely be used as a descriptive one for the so-called dysentery of amebic origin. In the first place, this condition is practically always chronic, in the sense of a protracted infection, and the acute types occasionally met may be looked on as mere exacerbations. The number of years the infection might exist in latent form, or, if established, remain unrecognized, is very variable and depends largely on the ability of the physician in making the diagnosis.

Among my series of 50 cases, in one the disease could be traced back twelve years, in another eight years, in 2 instances six years, and in 5 cases the condition had been present two years at the time of the first consultation. The average duration of the cases was about nine months.

The symptoms of amebic dysentery, as I have said, are not always clearly defined and constant. During its course there are quiescent periods, when apparently all trace of the trouble has vanished. The bowels might even become obstinately constipated. The amebæ remain, however, constantly under cover during this time, the infection suddenly flaring out again under conditions favoring renewed activity. These occasional attacks of diarrhea, alternating with periods of normal evacuations or constipation, make up a very suggestive picture of an amebiasis, and when present should lead to an immediate examination of the stools for the amebæ.

When attacks of diarrhea do occur, the number and character of the evacuations do not follow any set rule. A great deal depends on the location of the ulcers. If low down, and especially if in the rectum, the evacuations are usually frequent and a marked tenesmus, with soreness of the lower bowel, is noted. If the main lesions are above the sigmoid, as they most frequently are, the number of stools may never average above two to three per day. Mucus may or may not be present, but commonly is. Pure blood, or a blood-streaked mucus, I have found to be fairly constant, though at times in only small amounts. In one of my fatal cases, with liver abscess as a complication, the patient suffered severe hemorrhages, a symptom which, according to Strong, is always suggestive of abscess.

As far as the influence of age is concerned, the average in my cases was 37 years. This is in line with the usual figures given. The oldest of my patients was 60 and the youngest 22. The disease is rare among children, the dysenteric infections in early life being mostly of the bacillary type.

The colored race does not figure largely in my series, in which there were 42 whites and only 8 negroes. This, from a Southern city, in a non-selected field, is suggestive, as showing the relative infrequency of the disease among the blacks. Again, only 6 of the 50 patients were females, thus exhibiting a large preponderance of males affected. Occupation and the greater exposure of males to infection in general would, I believe, sufficiently explain this difference. Among my cases 25 were common laborers, 3 were farmers, 4 merchants, 2 bakers and 1 was a rabbi.

In the determination of the prevalence and endemicity of the disease in a particular locality, the nativity and immediate residence of the patients become of importance. Fifty per cent. of the patients I observed were born in Louisiana and had never lived in any other state or country, while an additional 14 per cent. had resided in Louisiana five years prior to the onset of the disease. In only two instances could the infection be traced definitely to the tropics. The remainder all came from neighboring Southern states. These figures, I believe, require no further comment in refutation of the views sometimes held that amebic dysentery rarely originates in this country and—more especially to the point—in the South.

The prognosis and, in a sense, the curability of this, as of other diseases, is largely determined by the period of its recognition. In a general way it may be said that the longer the infection has continued the greater probability there is of serious complication. Seventeen, or 28 per cent., of the fifty patients whose cases I have tabulated died. In 15 of these the cause of death was determined accurately by post-mortem. Extensive ulceration of the large bowel was found in practically all, but in nine instances this was found to be the sole cause of the fatal termination. Perforation was observed in but one case.

Six cases of abscess of the liver were recorded in these autopsy records, 5 solitary and 1 multiple. This complication is always an important and serious one. Figures differ, however, as to its frequency. In Futcher's cases, liver abscess was diagnosed in 22 per cent., in Craig's 33 per cent., and in Harris' only 15 per cent. All agree as to the infrequency of this condition in the female sex. All my patients were males. There is one point in connection with amebic liver abscess which I believe should be emphasized. The condition is looked for in the amebic infected districts all too rarely. The diagnostic puncture of the liver is always a simple procedure and is attended with practically no danger. Since the symptoms of an abscess are often so uncertain, the use of the aspirator is indicated when the merest grounds for suspicion are present. Only thus may a serious and often irretrievable oversight be avoided.

When we step now from the discussion of the purely clinical aspect of the amebic infections to a consideration of the organism itself, another chapter of almost equal importance spreads itself before us. The studies of recent years into the biologic and morphologic properties of the ameba have had, in fact, a highly important bearing on the solution of many of the hitherto vexed problems of the disease. Of these problems the principal have hinged on the question of the actual pathogenicity of the ameba to man, as well as on the separation, if such were possible, of a harmless from a disease-producing variety. It has been the lack of just such a differentiation in the past which has occasioned the degree of confusion in diagnosis and brought about the frequent false and contradictory reports in regard to the treatment. The earlier investigators recognized but one type of parasite, which, because of its connection with colonic infection, accidental or otherwise, they termed *Amœba coli* (Loesch). In 1891 Councilman and Lafleur, in their splendid studies, proposed that this name be dropped and that of *Amœba dysenteriæ* be substituted, since they believed that they had established a definite causal relationship between the ameba and the dysenteric lesions. They also hinted at the possibility of a non-pathogenic organism, for which the old term *Amœba coli,* they thought, might hold. Subsequently, several other forms of nomenclature were suggested, but it remained for Schaudinn, in 1903, following closely upon Jurgen's work, to announce the first definite and scientific classification of the amebæ. He retained the term *Entamœba,* previously suggested by Casigrandi, as the proper designation for the particular genus invading the intestine, but drew a sharp line of distinction between a type found pathogenic to man and cats, which he named *Entamœba histolytica* and a non-pathogenic, which he termed *Entamœba coli.*

Schaudinn's classification and conclusions have now been fully confirmed by the majority of competent observers, with the notable exception of Musgrave and Clegg, who still maintain that there is insufficient grounds for such a differentiation. The more recent, exhaustive studies of Craig, Viereck, Flexner and others leave little justification, however, for further doubt.

The two forms have many points of difference, both structural and bionomic, which allows of an easy differentiation between them.

This holds for native as well as stained preparations. I have found the Wright stain, as recommended by Craig, satisfactory.

Now that pure cultures of the *Entamœba histolytica* in guinea-pig serum has been found possible without symbiosis, a further insight into the life-history of this organism and its behavior under various conditions might be hoped for.

The question of the distribution of the *Entamœba coli* over the various regions of the world, as well as the proportion of healthy individuals infected with this apparently harmless parasite, are points which in part still remain open for further investigation and study. According to Craig, 71 per cent. of healthy individuals in the Philippines are found to harbor this organism, while the stools of 65 per cent. of the active soldiers stationed in San Francisco were likewise found infected. Schaudinn's figures, along the same line, average 50 per cent. for West Prussia, 20 per cent. for Berlin and 66 per cent. for those examined in the neighborhood of the Adriatic Sea. Dock, however, examined 200 normal subjects in Michigan and found the *Entamœba coli* in but two, or 1 per cent., of the whole. My own experiences in New Orleans, while not as yet based on a large or systematic scale in this field have indicated at least the relative infrequency of the *Entamœba coli* in Louisiana. The association of the harmless with the pathogenic type seems to be the rule in the Philippines; but I am yet to see an instance of this in our section.

In a large proportion of the stools I examined, however, *Cercomonas hominis* were found and in five of my cases I noted the *Strongyloides stercoralis* in connection with the *Entamœba histolytica.* Noe has recently called attention to this point and asserts that the so-called Cochin-China diarrhea, which was formerly thought to be solely due to a strongyloides infection, is in reality amebic dysentery, which in China is frequently complicated by the presence of the strongyloides worm.

TREATMENT

While substantial progress has been made, as we have seen, during the past half-century in almost every department of the subject of amebic dysentery, the matter of treatment still remains in almost as unsettled and undetermined state as before. There appears to be little chance, even to-day, with our advanced conceptions of the many phases of the disease and its problems for any unity of opinion as to the proper methods of its control. In the past, empiricism has been the sole guide and unfortunately holds sway to a great extent down to the present time. Every clinician would seem to hold individual ideas of the proper methods of treatment and those, too, largely irrespective of the experiences of others.

For hundreds of years ipecacuanha has been held in the highest esteem, above all other remedies, in East India and neighboring Oriental countries. This drug thus has at least the authority of longest usage and even to-day is regarded in Indian practice as almost a *sine qua non* in the treatment of amebic dysentery. Contrasted with this experience, however, there is a mass of contradictory testimony from other sources in which ipecac has seemingly been found totally inadequate. The experience of our army officers in the Philippines, for example, has always appeared particularly unfavorable to the use of ipecac. Strong, in his recent article in "Modern Medicine," discusses the ipecac treatment with a bare word, stating that the drug is "in no sense curative." Jackson is even more outspoken in his opposition. He says, in regard to this remedy, that he "has seen it thoroughly tried and is convinced of its utter uselessness and also of its harmfulness." From other countries, equally unfavorable experiences are recorded from time to time in the literature. Manson, however, always a great enthusiast in regard to the ipecac treatment, in his latest utterances on the subject, again puts forth a plea with his brethren in other lands, for another trial of this drug. Impressed with the weight of such high authority, and especially when born of so large an experience, I have ventured to employ ipecac in my cases during the past two years and am ready to acknowledge now my thorough conversion to the sanguine views of Manson and other English authorities in the tropics.

The detailed method of its administration is, I believe, of the greatest importance, the lack of which stands as explanation in part for the failures reported in some quarters. First of all, the drug should be administered only in pill form, coated to the extent of about an eighth of an inch with phenyl salicylate (salol). The patient must be put to bed for the first two weeks' treatment and his diet restricted to liquids or, at most, light solids. This absolute rest in bed, with restricted diet, is particularly essential to the details of the plan. Castor-oil may be given as an initial purgative and then each evening, after a three hours' fast, the pills coated with phenyl salicylate are administered. A start may be made with 40 or 60 grains, depending on the length or severity of the infection, but each subsequent evening the dose is reduced 5 grains, until the limit of 10 grains is reached. Following this, I have been in the habit of continuing with 10 grains each day for the next two weeks.

The use of the drug in this way has appeared to me almost in the light of a specific. Under its influence the stools become diarrheic, soft and pultaceous and the amebas seem to vanish almost at once, even though careful search be made for them. Opium is no longer required to prevent nausea or vomiting, if ordinary care be taken to have the pills well coated with phenyl salicylate.

The *modus operandi* of ipecac, which might account for the success following its administration, has never been satisfactorily explained. There is certainly nothing in the known physiologic effects of the drug which would suggest an explanation of its efficiency in this particular field. It seems plausible to infer, however, that ipecacuanha principles, through some intestinal changes, become inimical to the life of the amebas.

Bowel flushes, on which almost exclusive reliance is placed in some quarters, may or may not be employed in connection with the ipecac treatment. I prefer to make use of irrigations, however, principally as a means of washing away débris from the ulcerated bowel and begin with this procedure usually after the ipecac has been brought down to the limit of 10 grains per day. The character of the solution is not of great importance, so long as a sufficient quantity of water for thorough cleansing of the bowel is employed. Before my success with ipecac I had found all forms of solutions unsatisfactory. I believe simple saline solution fulfills the full requirements as a bland non-irritant bowel wash. As an after-treatment, nitrate of silver solutions may be indicated as a curative agent for the still remaining ulcerations.

What shall be said, finally, in regard to surgical intervention in intractable forms of the disease? The comparatively simple operation of appendicostomy, which, if properly performed, it is asserted, will permit a more satisfactory flushing of the large bowel, has found many advocates in this country in recent years. Its rationale, however, is not quite as clear as some enthusiasts of the plan would have us believe, and it is wise that the whole question be allowed to remain open for more extended trial and investigation.

1209 Maison Blanche Building.

ABSTRACT OF DISCUSSION

Dr. Thomas B. Futcher, Baltimore: In 1903, at the New Orleans Session of the American Medical Association, I analyzed our experience at the Johns Hopkins Hospital with cases of this disease during fourteen years, since the hospital was opened. At that time, there had been 119 cases of amebic dysentery in the wards. It was interesting to note that being not far north of the Mason and Dixon line, 95 of the 119 patients had never been out of the state of Maryland, and that the infection, therefore, must have been contracted there. The most important complication of the disease, of course, is amebic abscess of the liver. Among the 119 cases there were 27, or 22.6 per cent., amebic abscesses; 9 of these abscesses ruptured into the lung causing pulmonary abscess. One of these subsequently ruptured into the pleural sac, producing a pyopneumothorax; 3 of them had empyema. In 3 of the liver abscess cases the inferior vena cava was invaded. One case had a remarkable result; the abscess ruptured into the vena cava and there occurred a thrombus extending into the right auricle. This case has already been reported by Dr. Flexner. It is surprising, when we consider the extent and depth of the ulcers in this disease, that there are not more intestinal hemorrhages than do occur. There were but three instances of severe hemorrhage in our series of cases; all these had a fatal termination. There were 3 cases of perforation of the bowel, with a resulting peritonitis. One was recognized early and the patient was operated on, but died. There was one case in the wards in which an abscess was found in the floor of the mouth. The pus from the abscess contained ameba. This case has also been reported by Dr. Flexner. I wish to emphasize Dr. Simon's statement regarding the prevalence of the disease; I believe that it is of more frequent occurrence than is supposed. This disease can only be recognized by a most careful and systematic examination of the stools. There was one patient who came into the wards at Johns Hopkins four years ago suffering from diarrhea, in whom examinations of the stools gave negative results. Recently he again returned to the hospital and amebas were found in the stools. I have no doubt but that four years ago he had amebic dysentery. A careful and systematic examination of the stools should always be made, not once, but repeatedly. With reference to the operation of appendicostomy, that is, suturing the amputated appendix in the abdominal wound and irrigating the colon through this fistula, I would say that the results with us, so far, have been unsatisfactory, although our experience is limited. One man had appendicostomy performed Sept. 9, 1907; until April 14 of the following year, 1908, he had had daily irrigations of quinin solution, 1 to 500, and occasionally of nitrate of silver solutions, and of peroxid of hydrogen, etc. Only one month before he left the hospital did the amebas disappear from the stools. I have not been able to follow him since. This was certainly not a satisfactory result. There have been two other cases in the hospital in which appendicostomy has been performed without having given what we consider satisfactory results. Since Dr. Dock reported at this year's meeting of the Association of Tropical Medicine in Washington the results of the use of ipecac, Dr. Barker has employed it in two cases in his wards. Dr. Boggs told me yesterday that after the first dose a most thorough examination of the stools failed to reveal amebas. This is a remarkable result. I feel that the ipecac treatment ought to be given a thorough trial, so that we can see whether the results obtained are more satisfactory than are gotten by other methods. The ipecac is given in salol-covered pills, 20 grains to the dose, three times a day. Dr. Dock states that it may be given in smaller doses at shorter intervals, aggregating from 60 to 80 grains in twenty-four hours.

Dr. George Dock, New Orleans: The importance of the subject that Dr. Simon has brought up is realized by everybody who comes in contact with cases of chronic diarrhea. The geographical distribution of dysentery is certainly great; south of the latitude of Louisville, Ky., it is a very common disease. I reported a case occurring in the lower portion of Michigan in 1902. After that I discovered another case in northern Michigan; this patient had never been out of the county in which he lived. So the disease should be looked for wherever there is any chronic disturbance of the intestines. It is important for us to remember that a patient with chronic dysentery, true amebic dysentery, does not have the classical symptoms of dysentery all the time. The stools may appear normal for long periods of time. I should like to speak of some of the practical details in examining the stools of these patients. Ordinarily, it is easy to have a patient pass a stool at command. An examination of a stool with the naked eye is often unsatisfactory. Even an examination by the microscope may be negative. Therefore, in a negative case we should never be satisfied with a single examination or even with repeated examinations of ordinary stools. The next thing to do is to examine by rectum with a tube or speculum. t is better to pass the tube or speculum into the rectum; o use no grease on it, because it interferes with the examination. By working the instrument around, it will enter and sometimes we can get very positive information. If this examination should be negative, I think it is essential to give the patient a dose of salts, say Carlsbad salts, in order to produce watery stools. It is easy to understand by an examination of the intestine how a stool can be passed without amebas with it. The amebas lie in the abscesses or in the ulcers along the wall of the intestines and the stool passes by without mixing them in. I recall an interesting and instructive experience I had with a case that was diagnosed as amebic dysentery from the symptoms, yet was unable to find the amebas when the patient had a natural stool. A rectal tube was passed, but the patient complained so that it had to be removed. I then passed my finger into the rectum and got a lot of stuff which was filled with amebas. Why they were not forced out before I could only surmise. In the examination of the material it is not necessary to use a warm stage. Even in fairly cool weather the amebas keep up their activity for sometimes three or four hours. It is better, however, to examine them fresh; it is easier to detect them when they are lively. There is another point which I think should be mentioned. Beginners are easily led astray by the presence of large cells which they think are amebas. Red cells may be included in them. I have found people who had great difficulty in differentiating them.

I am glad that the success with the ipecac treatment has been confirmed by the results obtained in Dr. Barker's two cases. When we speak of results I must admit that many of the patients could not be followed up; so we could not be certain that they were entirely cured. Some patients have come back with the disease after weeks or months, four or five months, and we have not been able to find amebas, either with the aid of the rectal tube or speculum, or with the use of the Carlsbad salts. I recall the case of a man with the disease; he came from the Philippines and had been under treatment for two years; he had been given quinin, salicylic acid, etc. This patient was readily cured by the use of ipecac according to the method of Roberts. He was given 7 grams, or 105 grains, of ipecac in pills covered with salol. The amebas immediately disappeared from his stools. When he left the hospital I thought he might have a recurrence. He wrote me four years later and stated that he had "consumption." I supposed the amebic dysentery had returned with abscess of the liver, and I asked him to come back for examination. He returned and I found that he had tuberculosis. A very thorough examination of the stools failed to reveal any amebas. There were no signs of liver abscess. The failure of the operation of appendicostomy is what we should expect in some cases. The attempt to irrigate the colon through the cecum, washing downward, must fail in washing out the tube thoroughly. At all events, it would be well to try ipecac before resorting to an operation.

Dr. Hobart A. Hare, Philadelphia: I think that much interest in this discussion lies in the fact that thirty years ago Stillé taught his students to use ipecac at a time when they had no conception that amebas produced the disease. In May, I received a paper from Dr. Rogers of the Indian Medical Service practically repeating the facts already published in regard to the value of ipecac not only for the cure of dysentery but as a prophylactic against amebic abscess of the liver. The claims he makes for the prevention of hepatic complications by the employment of ipecac are so strong that, if his results are proved to be correct, the use of this agent should be resorted to in every case of amebic dysentery. The instances in which appendicostomy has proved of value constitute a class by themselves, a class in which the appendix acts as a focus of infection for the bowel. The cure does not follow from the irrigation used in the colon, but because it removes the focus of infection in the appendix. In a number of cases of so-called mucomembranous enteritis or colitis which seemed to be associated with neurasthenic conditions, I have seen the removal of the appendix result in a cure, simply because when the appendix was opened it was found to contain one or two drops of pus, and I have seen the physician in attendance disappointed because he thought the operation was going to be a failure so far as an ultimate cure was concerned, when in reality the removal of the infecting focus was exactly what was needed. And so in amebic cases, the appendix oozes out infection day by day. I am glad Dr. Dock spoke of the difficulty of irrigating the colon through the appendix; I am inclined to believe that this is no safe procedure. Some may remember that about twenty years ago experiments were made to determine just how much pressure the intestine could stand. It was proved that a pressure greater than that exercised by a fountain syringe placed twenty inches above the table was dangerous. This is the pressure we ordinarily get. This is more dangerous in a diseased gut, particularly when the lesions are ulcers the result of amebic infection. I agree that it is necessary to have proper technic in the use of ipecac. If not given properly it fails. Three or four surgeons returning to the United States from tropical countries have told me that this treatment only failed when the method of administration was erroneous. A very interesting point concerns the geographical distribution of the disease. Jefferson College Hospital is one of the largest in the country, more than 5,400 patients being admitted to the wards annually. There is a correspondingly large outdoor service. I have charge of these wards six months out of every year. I think I can remember but three cases of amebic dysentery occurring in the eighteen years that I have had charge of this service. We have a different service from that at the Johns Hopkins Hospital not only as regards dysentery, but as regards malaria, and yet we are only distant about one hundred miles. This difference is extraordinary. I am sure that the same conditions exist in other Philadelphia hospitals.

Dr. Hugo A. Freund, Detroit, Mich.: I can bear witness to Dr. Simon's statement about the widespread prevalence of dysentery. The cases are not necessarily endemic for it seems to me that they are coming from different portions of the globe. Last year I treated two cases of amebic dysentery that in some ways were of great interest. At the suggestion of Dr. Dock the first patient was treated with the salol-covered ipecac pills, 5 grains being given at a dose, and repeated every hour. But my method of administration differed somewhat from his. I first prepared the patient for medication. The first time the ipecac was given, 65 grains altogether, there was considerable diarrhea, tenesmus and pain. An examination of the stools the next morning, to my astonishment, revealed no amebas, nor could any forms resembling dead ones be found. For the next two weeks I gave the patient nothing but colonic irrigations; in addition the patient had rest, a soft diet, etc. In two weeks he was put through another course of ipecac, receiving a little more this time. All through there were no amebas in the stools, the patient experienced very little pain. In another week he was given 80 grains more of salol-covered ipecac pills. That was last November. Seven months have elapsed and the patient has gained in weight and feels very different since his infection. To all intent and purposes he is absolutely well. In this case the interesting feature was the degree of ulceration in the lower bowel which could easily be seen with the sigmoidoscope. These ulcers are entirely healed. His stools are normal in gross appearance and in the course of repeated examinations I have never found a sign of an ameba. The other patient was a young soldier from the Philippines. He received a typical course of treatment, being given large doses of salol-covered ipecac pills. This patient was also irrigated because I felt that some benefit would result from flushing the large bowel. He, too, is well. I am sure that there are other cases like this in different parts of the country as far north as Michigan, but we fail not only to recognize these cases, but also to treat the patients by what I believe to be the only satisfactory method, namely, administration of large doses of ipecac.

Dr. James P. Tuttle, New York: It is well to hear both sides of a subject such as this—the surgical as well as the medical. We who have had more experience in the local treatment of these conditions than those who have participated in the discussion thus far know that the results of local measures and of appendicostomy have been maligned here this afternoon; all our patients come to us for local measures and appendicostomies after failure to cure by medical measures alone. I have seen true amebic dysentery develop in people who had never been outside of a fifty-mile radius of New York City, and there is no longer any doubt that the disease is frequent high up in the temperate zones. A patient was sent to me for diagnosis who had been treated by physicians in Philadelphia, Baltimore, Richmond and New York. All these men had amebic dysentery in view, but they had failed to discover the amebas. I took the patient and made a very careful local examination and could only find some small scars in the rectum, apparently such scars as are seen after dysentery. I sent this patient to the hospital and placed him in the laboratory. He was given large doses of salts and was told to stay there until his bowels moved. He remained there five hours and yet there occurred no movement of the bowel. The next day this was repeated and we got a stool in which was a mass said to be about the size of the thumb nail, which was alive with motile amebas. The stools must be examined in a fresh state and warm; also every stool should be strained in order to get the little mucus flakes in which the amebas are found. The patient, mentioned by Dr. Fletcher, who was operated on at Johns Hopkins Hospital, and in whom the appendicostomy failed to cure, turned up afterward in my office. I followed this patient carefully. In the appendix I found a rubber tube which had become almost vulcanized from being left in too long, and which stuck down five inches into the cecum. There were ulcers around the end of the tube where it was pressing. I also found in the lower end of the rectum a number of ulcers, not amebic at all, but the result of mixed infections, which did not require amebic treatment. They required simply local treatment for the subsequent infection which had followed the amebic infection. This was a traumatic ulcer and cure resulted from simple local treatment. I disavow any desire to perform an appendicostomy on an individual with amebic dysentery until there has been tried Epsom salts, ipecac, local washings with quinin solutions, etc. I do not think it makes much difference what solution is used so long as the temperature is below 70 F. I am using a different method. I do not advise operation until I have tried local treatment. But when I fail with the use of the local treatment and the patient comes back again in four or five months and shows that I have not reached the seat of the amebic infection, then I may propose operation. Washing out the colon through the appendix is effectual; it gives no mortality, while the reader of the paper confesses to a mortality of 17 per cent. under medical treatment. Over 125 of these patients have been treated in New York City, with but one death. This patient died from acute miliary tuberculosis after an appendicostomy. Not less than twenty officers of the United States Army, treated with ipecac and other medicines, were not cured; they then said, if these agents fail, let us try appendicostomy and see if we cannot be cured. The trouble with so many appendicostomy operations is that the operation is not done as it should be; an infection occurs around the end of the appendix which, as a result, slips back into the abdomen. Another thing is that the opening is closed too quickly. In the United States Army men the openings are usually closed inside of three months. I never close them inside of six months, and in the majority of cases I leave them open permanently. The opening is a safety valve. It is easy to get a stool by running warm saline solution through the fistula. I only advise operation as a last resort. Recently I have had three patients with amebic dysentery. I treated them by administering a formalin solution, one dram to a quart of water; along with full doses of tannopin by mouth. After the administration of the medicines and washing out the bowel I have not been able to see any amebas after forty-eight hours' treatment in any one of these three cases. These patients have been under treatment four months, two months and one month respectively. So far there have been no recurrences. I am inclined to believe, however, that it would be well to use local irrigations and at the same time use ipecac.

Dr. Samuel G. Gant, New York: I wish to confirm Dr. Tuttle's statements regarding the usefulness of appendicostomy in the treatment of both the amebic and bacillary types of dysentery. This operation, however, would not be necessary except in rare instances in this class of cases if thorough colonic irrigations could be obtained otherwise. There is but a small number of medical practitioners, hospital internes and nurses who could effectively introduce the colon tube and wash out the bowel. Lack of training renders many unable to pass the tube beyond the obstructions offered by the sphincter muscle, rectal valves, and the angulation at the rectosigmoidal juncture. When the colon tube cannot be made to enter the upper part of the large intestine in the ordinary way, the sigmoidoscope should be introduced and the tube passed through it. Low irrigations diminish the number of stools but high washing of the bowel is imperative when a cure is anticipated. One must go even a step farther than this and place the patient in the Trendelenburg posture and then change him from one position to another to make the irrigation complete, because if this is not done the fluid will flow along one side of the gut and leave the lesions on the other untouched. In my opinion, the temperature of the solution has nothing to do with the healing quality of the irrigation and I prefer it at the bodily temperature because it is more comfortable; I have discontinued ice cold solutions because of the shock and great suffering which their employment frequently induces. I have successfully treated patients suffering from dysentery with solutions containing salt, quinin, ichthyol, kramaria, hydrastis, boric acid, permanganate of potash, formalin, silver nitrate and other medicaments in varying strengths, and I believe that the greatest benefit derived from any irrigating fluid is due to its mechanical effect in cleansing the ulcers and removing toxins from the bowel. When the discharge is profuse and contains considerable pus and blood, in the beginning I prefer to wash the bowel out daily with a solution containing from 20 to 30 grains of silver nitrate to the quart, to be followed by flushing the bowel with a normal salt solution to lessen the tenesmus when necessary; when the movements have a very offensive odor, I correct this and encourage the ulcers to heal rapidly by employing a 2 per cent. solution of ichthyol. I hold that the dysenteric lesions in a few cases involve the lower ileum and that in others the dysentery has become grafted on an enterocolitis, and that under such circumstances it is imperative that the irigating fluid be made to reach the few lesions in the small bowel as well as the many ulcers in the colon. In such instances, and in cases in which, for any reason, the appendix is found unfitted for through and through irrigation, I recommend cecostomy, which provides a simple means of irrigating both the small and the large intestine, a procedure which has proved universally successful in my hands. So far as my experience goes, appendicostomy and cecostomy are far superior to diet, rest and all forms of medication, not only in dysentery, but in other types of colitis; and these surgical procedures should not be discarded in favor of the special treatment as many of the previous speakers would have us believe.

Dr. Sidney K. Simon, New Orleans: Our surgical friends have certainly added much of timely interest and value to the discussion of this important subject. At first it appeared we were going to have merely a love feast with ipecac as almost the sole article of diet. I believe that ipecac is best administered in one large dose, given in the evening, after a three-hours' fast. The plan of giving 5 grains, or 10 or 20 grains, three times a day, is not so good in my opinion as the one large dose. Formerly we also used opiates, but the employment of the salol-covered pill makes this in most instances unnecessary. I agree with Dr. Tuttle about finding the amebas in the warmed stools only. Neither do we find it necessary to strain the feces or to pick out the mucous flakes. On the there is any chronic disturbance of the intestines. It is important for us to remember that a patient with chronic dysentery, true amebic dysentery, does not have the classical symptoms of dysentery all the time. The stools may appear normal for long periods of time. I should like to speak of some of the practical details in examining the stools of these patients. Ordinarily, it is easy to have a patient pass a stool at command. An examination of a stool with the naked eye is often unsatisfactory. Even an examination by the microscope may be negative. Therefore, in a negative case we should never be satisfied with a single examination or even with repeated examinations of ordinary stools. The next thing to do is to examine by rectum with a tube or speculum. t is better to pass the tube or speculum into the rectum; o use no grease on it, because it interferes with the examination. By working the instrument around, it will enter and sometimes we can get very positive information. If this examination should be negative, I think it is essential to give the patient a dose of salts, say Carlsbad salts, in order to produce watery stools. It is easy to understand by an examination of the intestine how a stool can be passed without amebas with it. I am sure that there are other cases like this in different parts of the country as far north as Michigan, but we fail not only to recognize these cases, but also to treat the patients by what I believe to be the only satisfactory method, namely, administration of large doses of ipecac.

Dr. James P. Tuttle, New York: It is well to hear both sides of a subject such as this—the surgical as well as the medical. We who have had more experience in the local treatment of these conditions than those who have participated in the discussion thus far know that the results of local measures and of appendicostomy have been maligned here this afternoon; all our patients come to us for local measures and appendicostomies after failure to cure by medical measures alone. I have seen true amebic dysentery develop in people who had never been outside of a fifty-mile radius of New York City, and there is no longer any doubt that the disease is frequent high up in the temperate zones. A patient was sent to me for diagnosis who had been treated by physicians in Philadelphia, Baltimore, Richmond and New York. All these men had amebic dysentery in view, but they had failed to discover the amebas. I took the patient and made a very careful local examination and could only find some small scars in the rectum, apparently such scars as are seen after dysentery. I sent this patient to the hospital and placed him in the laboratory. He was given large doses of salts and was told to stay there until his bowels moved. He remained there five hours and yet there occurred no movement of the bowel. The next day this was repeated and we got a stool in which was a mass said to be about the size of the thumb nail, which was alive with motile amebas. The stools must be examined in a fresh state and warm; also every stool should be strained in order to get the little mucus flakes in which the amebas are found. The patient, mentioned by Dr. Fletcher, who was operated on at Johns Hopkins Hospital, and in whom the appendicostomy failed to cure, turned up afterward in my office. I followed this patient carefully. In the appendix I found a rubber tube which had become almost vulcanized from being left in too long, and which stuck down five inches into the cecum. There were ulcers around the end of the tube where it was pressing. I also found in the lower end of the rectum a number of ulcers, not amebic at all, but the result of mixed infections, which did not require amebic treatment. They required simply local treatment for the subsequent infection which had followed the amebic infection. This was a traumatic ulcer and cure resulted from simple local treatment. I disavow any desire to perform an appendicostomy on an individual with amebic dysentery until there has been tried Epsom salts, ipecac, local washings with quinin solutions, etc. I do not think it makes much difference what solution is used so long as the temperature is below 70 F. I am using a different method. I do not advise operation until I have tried local treatment. But when I fail with the use of the local treatment and the patient comes back again in four or five months and shows that I have not reached the seat of the amebic infection, then I may propose operation. Washing out the colon through the appendix is effectual; it gives no mortality, while the reader of the paper confesses to a mortality of 17 per cent. under medical treatment. Over 125 of these patients have been treated in New York City, with but one death. This patient died from acute miliary tuberculosis after an appendicostomy. Not less than twenty officers of the United States Army, treated with ipecac and other medicines, were not cured; they then said, if these agents fail, let us try appendicostomy and see if we cannot be cured. The trouble with so many appendicostomy operations is that the operation is not done as it should be; an infection occurs around the end of the appendix which, as a result, slips back into the abdomen. Another thing is that the opening is closed too quickly. In the United States Army men the openings are usually closed inside of three months. I never close them inside of six months, and in the majority of cases I leave them open permanently. The opening is a safety valve. It is easy to get a stool by running warm saline solution through the fistula. I only advise operation as a last resort. Recently I have had three patients with amebic dysentery. I treated them by administering a formalin solution, one dram to a quart of water; along with full doses of tannopin by mouth. After the administration of the medicines and washing out the bowel I have not been able to see any amebas after forty-eight hours' treatment in any one of these three cases. These patients have been under treatment four months, two months and one month respectively. So far there have been no recurrences. I am inclined to believe, however, that it would be well to use local irrigations and at the same time use ipecac.

Dr. Samuel G. Gant, New York: I wish to confirm Dr. Tuttle's statements regarding the usefulness of appendicostomy in the treatment of both the amebic and bacillary types of dysentery. This operation, however, would not be necessary except in rare instances in this class of cases if thorough colonic irrigations could be obtained otherwise. There is but a small number of medical practitioners, hospital internes and nurses who could effectively introduce the colon tube and wash out the bowel. Lack of training renders many unable to pass the tube beyond the obstructions offered by the sphincter muscle, rectal valves, and the angulation at the rectosigmoidal juncture. When the colon tube cannot be made to enter the upper part of the large intestine in the ordinary way, the sigmoidoscope should be introduced and the tube passed through it. Low irrigations diminish the number of stools but high washing of the bowel is imperative when a cure is anticipated. One must go even a step farther than this and place the patient in the Trendelenburg posture and then change him from one position to another to make the irrigation complete, because if this is not done the fluid will flow along one side of the gut and leave the lesions on the other untouched. In my opinion, the temperature of the solution has nothing to do with the healing quality of the irrigation and I prefer it at the bodily temperature because it is more comfortable; I have discontinued ice cold solutions because of the shock and great suffering which their employment frequently induces. I have successfully treated patients suffering from dysentery with solutions containing salt, quinin, ichthyol, kramaria, hydrastis, boric acid, permanganate of potash, formalin, silver nitrate and other medicaments in varying strengths, and I believe that the greatest benefit derived from any irrigating fluid is due to its mechanical effect in cleansing the ulcers and removing toxins from the bowel. When the discharge is profuse and contains considerable pus and blood, in the beginning I prefer to wash the bowel out daily with a solution containing from 20 to 30 grains of silver nitrate to the quart, to be followed by flushing the bowel with a normal salt solution to lessen the tenesmus when necessary; when the movements have a very offensive odor, I correct this and encourage the ulcers to heal rapidly by employing a 2 per cent. solution of ichthyol. I hold that the dysenteric lesions in a few cases involve the lower ileum and that in others the dysentery has become grafted on an enterocolitis, and that under such circumstances it is imperative that the irigating fluid be made to reach the few lesions in the small bowel as well as the many ulcers in the colon. In such instances, and in cases in which, for any reason, the appendix is found unfitted for through and through irrigation, I recommend cecostomy, which provides a simple means of irrigating both the small and the large intestine, a procedure which has proved universally successful in my hands. So far as my experience goes, appendicostomy and cecostomy are far superior to diet, rest and all forms of medication, not only in dysentery, but in other types of colitis; and these surgical procedures should not be discarded in favor of the special treatment as many of the previous speakers would have us believe.

Dr. Sidney K. Simon, New Orleans: Our surgical friends have certainly added much of timely interest and value to the discussion of this important subject. At first it appeared we were going to have merely a love feast with ipecac as almost the sole article of diet. I believe that ipecac is best administered in one large dose, given in the evening, after a three-hours' fast. The plan of giving 5 grains, or 10 or 20 grains, three times a day, is not so good in my opinion as the one large dose. Formerly we also used opiates, but the employment of the salol-covered pill makes this in most instances unnecessary. I agree with Dr. Tuttle about finding the amebas in the warmed stools only. Neither do we find it necessary to strain the feces or to pick out the mucous flakes. On the contrary, all parts of the stool should be examined, as the mucous flakes do not always contain the largest number of amebas. I was not correctly understood regarding the mortality figures. Fifty cases were reported, mostly from hospital records, and not all my own, so that the treatment varied. In every patient not moribund treated by me with ipecac, the mortality has been nil. There is a certain tendency to recurrence in this as in all bowel infections. This should be explained to the patient with the understanding that perhaps a second course of treatment will be necessary. In one of my cases with a clear amebic history of eight years' standing, there has been no recurrence for one year following the second ipecac treatment. *After the patients have once been freed of amebas it is important to instruct them to boil the water they use to obviate the dangers of reinfection.* After these patients are cured in the hospitals they might return to their former residence only to become reinfected with the original contaminated water supply. I trust that I have made clear the two points I wished especially to emphasize: the prevalence of the ameba over the entire country, and especially in the south, and the proved value of the ipecac treatment, rendering surgery in most instances unnecessary.

A RATIONAL AND SIMPLE SYSTEM OF SERODIAGNOSIS OF SYPHILIS *

HIDEYO NOGUCHI, M.D.
Associate Member of the Rockefeller Institute for Medical Research
NEW YORK

In a rationally constructed complement fixation test the quantity of each reagent should be known and definite. The relative quantities of the different factors used should also be definite and suitable. The reasons why these principles should be respected will be apparent.

First, let us study the properties of hemolytic amboceptor and complement. When present together amboceptor and complement dissolve the blood corpuscles for which the amboceptor used possesses a specific affinity. The process of hemolysis is, however, a quantitative one. To dissolve a given bulk of corpuscles requires a definite amount of amboceptor and complement; and the quantity of these two reagents just sufficient to cause complete hemolysis within a time limit represents the unit of these hemolytic components relatively to each other. Expressed graphically:

1 unit corpuscles + 1 unit amboceptor + 1 unit complement = complete hemolysis.

There exists, however, a peculiar relationship between the requisite amounts of amboceptor and complement necessary to produce complete hemolysis of one unit of corpuscles. If we use more than one unit of amboceptor, less than one unit of complement will be sufficient to cause complete dissolution of the corpuscle mass. So that if, for instance, ten units of amboceptor be added, *one-fifth or even less of the unit of complement* will be sufficient; or, in other words, the requisite amount of complement can be gradually reduced if the amboceptor quantity is at the same time increased, until finally we reach the minimal amount of complement, to the addition of which no quantity of amboceptor will cause complete hemolysis. With this fundamental fact of the quantitative relationship between complement and amboceptor[1] in mind, it will be evident that the degree of hemolysis does not indicate the *absolute* quantity of complement operative in the hemolytic process. It indicates merely a *relative* quantity which varies with the quantity of amboceptor used in each instance. There-

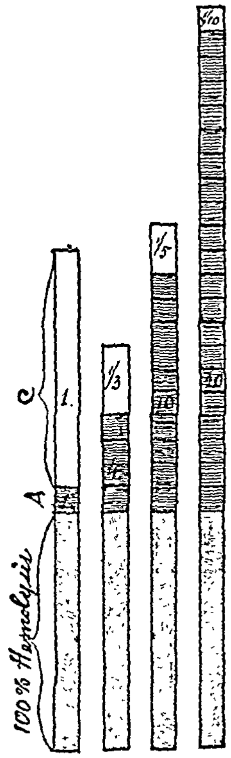

Fig. 1.

Fig. 1.—Shows that complete hemolysis can be produced by using variable proportions of amboceptor and complement. A, amboceptor; C, complement; H, hemolysis. The figures in lined zones indicate the number of units of amboceptor, and those in blank zones, the quantity of complement required in each combination.

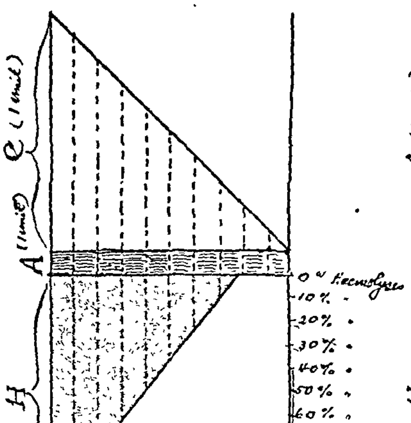

Fig. 2.

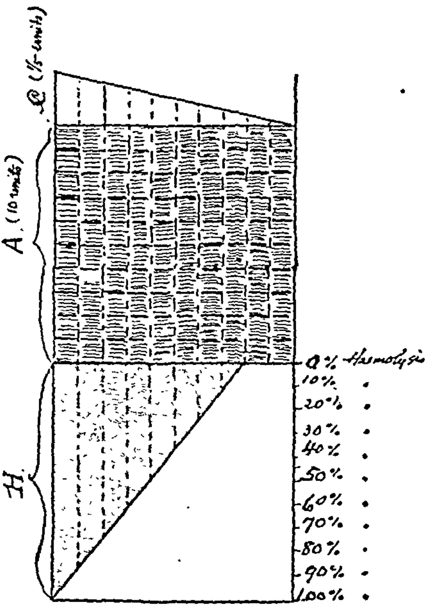

Fig. 3.

Fig. 2.—Shows the decreasing degree of hemolysis by using decreasing quantities of complement with one unit of amboceptor.

Fig. 3.—Shows decreasing degree of hemolysis produced by using less complement and more amboceptor (10 units). These two figures demonstrate that exactly the same degree of hemolysis can be produced by widely different quantities of complement according to the relative amount of amboceptor used.

---

* Read in the Section on Pathology and Physiology of the American Medical Association, at the Sixtieth Annual Session, at Atlantic City, June, 1909.

[1] Morgenroth and Sachs: Berl. klin. Wchnschr., xxxix, 817. Noguchi: Jour. Exper. Med., 1906, viii, 87.

fore, no one can measure even approximately the quantity of complement in action, unless he knows the amount of amboceptor present. Without this factor an estimation of the amount of complement by the degree of hemolysis is out of the question (Figs. 1, 2 and 3).

In the complement fixation test the deviation of complement is estimated by the phenomenon of hemolysis. If complement is fixed or deviated there will be no hemolysis, but the absence of hemolysis may be due either to partial or to total fixation of complement. In case of partial fixation the remaining fraction of complement may become sufficiently active to produce complete hemolysis if an excess of amboceptor is present. Thus we can obtain a negative result with a positive syphilitic serum in the presence of such an excess. That such a fallacious reaction is not merely a theoretical possibility but is frequently encountered in practice can be demonstrated experimentally. It is, therefore, absolutely necessary that a definite and appropriate quantity of complement and amboceptor be used in the test. The strength of corpuscle emulsion should also be approximately uniform.

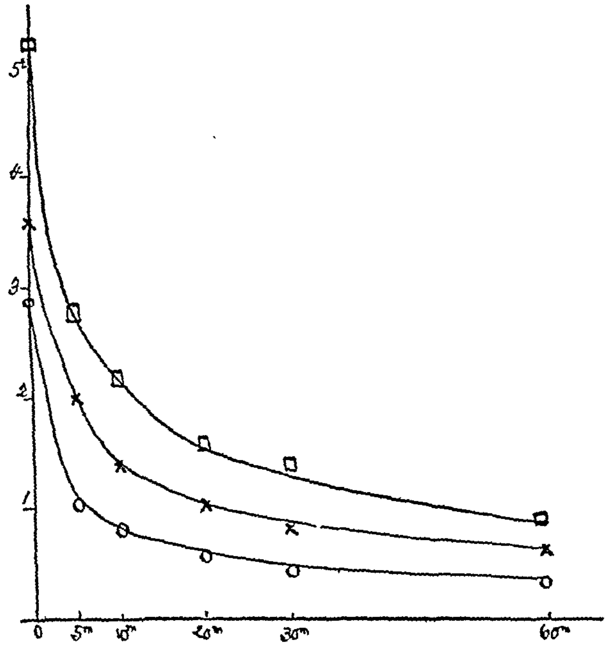

Fig. 4.—Curves indicating destructive influence of inactivation (55° C.) on the syphilitic "antibody." The small squares indicate serum from an untreated secondary syphilis; the crosses indicate serum from a case of chancre; the circles indicate serum from a manifest case of tertiary syphilis. The base line shows the length of time in minutes of exposure of the serums to that temperature. The side line shows the quantity of "the antibody" originally contained in each specimen. The curves show the rapidity of destruction of the antibody.

In regard to antigen, it should be borne in mind that all preparations of this substance possess not only an antigenic property, but also an anticomplementary one, and if the anticomplementary action be present in excess in any given preparation it renders the material unfit for use, because it may cause complete fixation even without the presence of any syphilitic antibody. Therefore, we should select by trial a preparation in which this anticomplementary action is reduced to a minimum and use that dose which does not by itself bind complement, but which will cause complete fixation with the serum of an untreated subject of secondary or tertiary syphilis.

Aqueous extracts of the liver of a congenitally syphilitic fetus contain an excess of antigen over anticomplementary property, as do alcoholic extracts, but in the former the anticomplementary action exceeds that of the latter.

The antigenic property of any tissue is due to certain lipoids present in it, lecithin being but one of a large number of such bodies. The aqueous extract contains, in addition to these lipoids, bodies of a protein and fatty nature, which render it very unstable and subject to rapid disappearance of the antigenic property. The alcoholic extracts, on the other hand, while they contain considerably less anticomplement and are much more stable, rarely deteriorating, may contain hemolytic substances, such as soaps, fatty acids, etc. Fortunately, according to my experience, the antigenic substances can be separated from both the anticomplementary and hemolytic by fractioning the dried alcoholic residue with acetone, the disturbing factors going over in the soluble portion. The insoluble fraction, containing the antigenic property, can be preserved indefinitely as a resinous mass or in alcoholic solution. The latter can then be used as an emulsion in salt solution as required, when, however, it is subject to the same rapid deterioration as the watery extract or the alcoholic extract after the latter has been emulsified for use in doing the test.

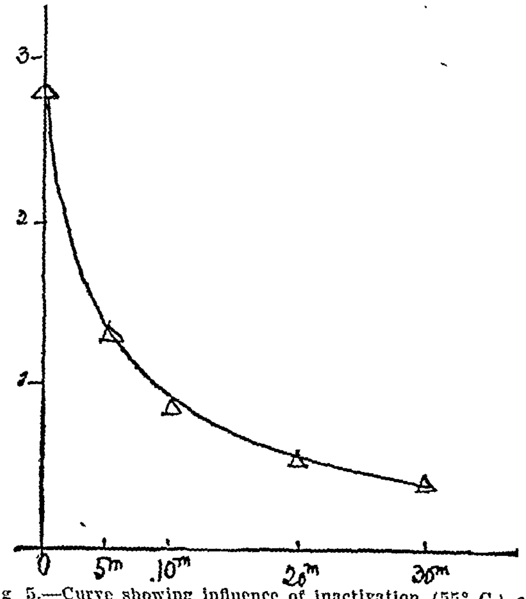

Fig 5.—Curve showing influence of inactivation (55° C.) on the reacting substance of leprosy serum.

Paper may be impregnated with acetone insoluble fraction of the alcoholic extract, and this paper will retain its antigenic property indefinitely.

It may be said that the irregular and unsatisfactory results from the use of alcoholic extracts can be attributed, at least in part, to the disturbing factors pointed out above and the uncertainty of the concentration of any given preparation. The acetone insoluble fraction, however, as pointed out above, can be dried and definite quantities used. It contains antigenic properties in comparatively pure condition. This acetone insoluble fraction as derived from various organs differs only in quantity, the quality of the preparations being practically the same.

Concerning the quantity of the serum to be tested, it is necessary to distinguish between unheated and heated serum, because inactivation at 56° C. for thirty minutes reduces the antibody content to 20 or 25 per cent. of that originally present in the fresh state. Hence, to obtain comparable results, it is necessary to use four or five times as much inactivated serum as unheated serum.

In certain systems in order to utilize the patient's own complement the serum is used in considerable quantity in the unheated state (practically as much as is used in the Wassermann system, 0.1 or 0.2 c.c.), and these systems frequently are oversensitive. This source of error can be eliminated by carefully adjusting the dose of serum to be used. Hence the criticism of certain investigators in relation to this point is valid only if an excess of unheated serum is used. I present in Figures 4, 5 and 6 some of the curves of the rate of destruction of the so-called syphilitic antibody by exposure to different temperatures for variable lengths of time. The curves were taken by examining each serum for the antibody content before and after heating by means of complement fixation.

From what has been said above it will be seen that it is essential to analyze each individual factor concerned in the test, to be able to determine, if necessary, its quality as well as its strength. Complement, amboceptor, corpuscular emulsion and antigen should be of known strength. Each of these substances must be separable from the rest, titrable and a proper combination of all should be used.

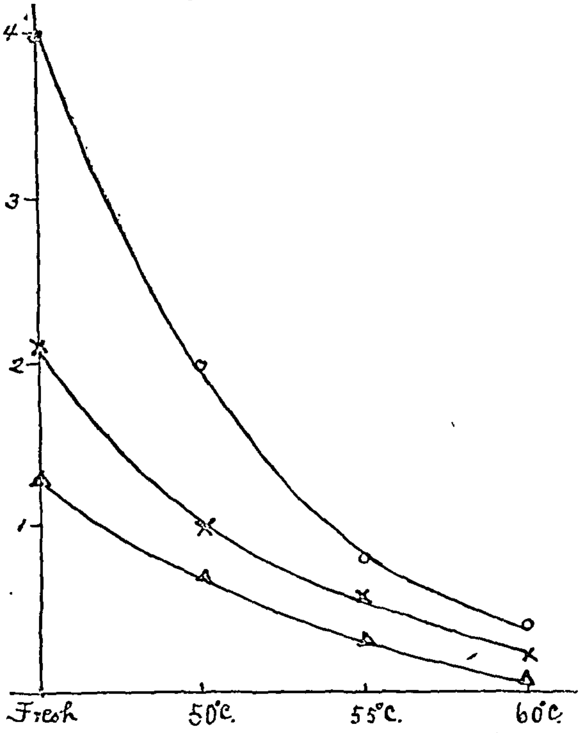

Fig. 6.—Curves showing influence of different temperatures on the syphilitic "antibody." Time of exposure thirty minutes at each temperature. Circles indicate serum from a case of secondary syphilis; crosses indicate serum from a case of primary syphilis; triangles indicate serum from a case of tertiary syphilis.

In the methods introduced to the profession by the various investigators certain defects are inherent and irremovable, as will be pointed out further on, rendering the tests more or less open to objection.

It will be apparent to all that in the complement fixation test we are dealing with variable factors and with reagents subject to deterioration in the hands of the most experienced workers, which will, in a measure at least, account for the discrepancies of the results of different investigators. Hence the value of any system rendering the use of stable reagents possible is evident.

It is my purpose now to consider the various forms of this test as applied to the diagnosis of syphilis.

1. Group of Systems in Which Foreign Corpuscles Are Used

A. Wassermann-Neisser-Bruck System.—Guinea-pig complement titrable and definite. Amboceptor of unknown and variable quantity. *From two sources: one irremovably present in* the patient's serum and varying from 0 to 20 units, the other added, from rabbits immunized to sheep's corpuscles, two units. Corpuscle suspension (sheep's) definite. Serum to be tested must be inactivated within twenty-four hours before use. Antigen may deteriorate rapidly. Only one fault: the use of an unknown quantity of amboceptor, which, if sufficiently excessive, may render a positive case negative.

B. Bauer's System.—Same as the previous except that it relies on the natural anti-sheep amboceptor of human serum. Occasional absence of this factor adds a further defect.

C. Hecht's System.—Relies on complement and amboceptor present in patient's serum; hence both factors unknown, *untitrable, inseparably mixed. In a syphilitic serum no direct* way to estimate accurately the anticomplementary strength of antigen alone because of presence of syphilitic antibody. Test must be made within twenty-four hours, because complement gradually diminishes. Washed sheep's corpuscles used. The amount of patient's serum comparatively too large, but can not be reduced, as it would also reduce the amount of complement at the same time. All defects of the foregoing systems as well.

D. Stern's System.—Same as C, except that immune anti-sheep amboceptor is added. Similar defects.

E. Detre's System.—Rabbit complement. Immune anti-horse amboceptor in definite quantity. Washed horse corpuscles. *Inferior sensitiveness of rabbit's complement to fixation,* and occasional presence of the natural amboceptor in the serum to be tested.

2. Group of Systems in Which Human Corpuscles Are Used

A.—Tschernogubow's System.—Patient's blood directly dropped into saline solution. Complement, corpuscles *and antibody*, if present, all in same medium. None of these three factors titrable because inseparable. Specimen must be examined within twenty-four hours. Quantity of various factors inadjustable. System discarded by its author.

B. Noguchi's System.—Each factor is separable, titrable, definite. The proportional quantity of each factor adjustable. Complement from guinea-pig.[2] Can be used in fresh as well as dried state. Latter more stable; former preferable if obtainable. Amboceptor from rabbit immunized to human corpuscles and can be used in liquid state as well as dried on paper; latter more stable. Corpuscle suspension can be made from the blood of patient or any normal individual. Removal of serum by washing corpuscles preferable but not necessary unless fibrin ferment present. Patient's serum can be used in fresh, old or inactivated state and if necessary serum can be dried on filter-paper and examined after an indefinite length of time. Antigen prepared from normal or syphilitic tissues by alcoholic extraction and subsequent acetone fractionation. Can be made more stable by impregnating filter-paper. *No danger of introducing excess of* amboceptor or complement. Quantity of serum to be tested is very small and so adjusted as to avoid oversensitiveness. *When inactivated, four to five times the amount used.* Test, like all the others, requires a trained man, but not a fully equipped laboratory as is necessary with all the other systems. For details consult my previous publications.[3]

In a paper read before the Section on Nervous and Mental Diseases of this Association at this session,[4] I reported the results of about 1,800 cases analyzed by my system and 600 cases by the original Wassermann method, together with a comparative study of 244 cases examined by both these methods.

---

[2] The complement contained in human serum is so weak that it does not interfere with the test.

[4] The Journal A. M. A., Sept. 18, 1909.

The Wassermann method is cumbersome and requires elaborate facilities and considerable experience for its proper execution and is utilizable in practice only to a limited extent.

The method which I have worked out is simple, requires a small and inexpensive equipment, can be applied after a little instruction, and, above all, gives a result more uniform and reliable.

SOME STUDIES OF THE PRECIPITIN TESTS FOR SYPHILIS *

HENRY S. WIEDER, M.D.
AND
EDWARD M. L'ENGLE, M.D.
Demonstrator of Surgical Pathology, and Demonstrator of Pathology, Respectively, in the Medico-Chirurgical College
PHILADELPHIA

Since the epoch-making discovery of the *Treponema pallidum* by Schaudinn interest in the scientific diagnosis of syphilis, as opposed to the clinical diagnosis, has received a remarkable impetus, so that to-day almost all the more important laboratories of the world have some of their workers devoting their attention to this subject.

Probably the first and most successful result of these numerous investigations was the test described by Wassermann and since confirmed by numerous other investigators, using his test or some modification of the same. The results obtained by Wassermann and those using his test have been remarkably good, from 78 to 88 per cent. of syphilitic and parasyphilitic cases giving a positive reaction, whereas the non-syphilitic cases are negative in practically all, except some advanced cases of tuberculosis, carcinoma and sepsis.[1]

While these tests are extremely valuable from the scientific point of view, they are absolutely useless to the general practitioner and to the average laboratory worker owing to the complicated technic. The practical applicability of this test has probably been obtained recently by Noguchi with his simplified tests by the means of saturated papers, the complicated portion of the technic being performed in well-equipped commercial laboratories and the results of this work handed to the practitioner in condensed form.

Before Noguchi had elaborated this modification of the Wassermann test other investigators had been trying to simplify it by eliminating one or more factors in the experiment. The first and only modification which has any bearing on our work was when it was found that an alcoholic extract of syphilitic liver of a fetus would answer the purpose of an antigen as well as fresh extract of syphilitic fetal liver and could be preserved indefinitely. This discovery led to the investigation as to what could be the active factor in this alcoholic extract: it was found to contain merely bile salts.

Utilizing these bile salts, an effort was made still further to simplify the test by eliminating the necessity of demonstrating the deviation of the complement and endeavoring to obtain some direct specific action between the serum of syphilitic patients and solutions of the various bile salts. The reaction that was found to occur was the formation of precipitates which, according to some, were found to form earlier in syphilitic cases than in normal cases, and also to differ slightly in character. Preeminently among those claiming specificity for this reaction, especially with a bile salt called taurin, is Varney of Detroit. By his method he believes it possible to determine the presence of syphilis in about 87 per cent. of cases and believes that it is possible to determine if patients that have positively had syphilis and have been treated, have been cured.

Klausner, antedating Varney, found that he could obtain a precipitate early in 100 per cent. of syphilitics by the addition of 0.7 c.c. of distilled water to 0.2 c.c. of serum. He found, however, that a certain proportion of cases not syphilitic gave a similar reaction. These cases were mostly acute febrile conditions, so that they would not be liable to lead to confusion, therefore making the test of considerable value from his point of view. He considers the precipitate to be composed of globulins, which are present in excess in syphilis, and therefore thrown down early.

It is for the purpose of confirming, if possible, the above experiments that the studies were undertaken on which this article was based. Five different sets of experiments have been performed in which the following aqueous solutions have been used: 1 per cent. taurocholate of sodium, 1 per cent. glycocholate of sodium, 1 per cent. lecithin, 1 per cent. taurin and distilled water. In all, 54 cases were studied: 11 secondary syphilitics, 5 tertiary syphilitics, 18 parasyphilitics (17 paretics and 1 tabetic) and 20 non-syphilitics, including 2 cases with jaundice, 1 tuberculous peritonitis, 1 puerperal case, 1 suppurative appendicitis, 3 neurasthenics, 1 case of sciatica, 1 case of chancroid with adenitis, 1 case of gonorrhea, and 10 practically normal. These cases were obtained through the kindness of the chiefs at the Philadelphia General Hospital and Insane Department; also at the Medico-Chirurgical Hospital and the Genitourinary Department of the Polyclinic Hospital, and we wish to express our gratitude to all of these for permission to study the cases.

Altogether, 253 observations were made, including all experiments. The experiments consisted in adding one drop of serum to seven drops of the reagent. Observations were made from five to seven and one-half hours later and then at the end of eighteen hours. In our conclusions, we have found that the observations made at the end of eighteen hours are of no value, as practically all cases give identical results in that time, so these observations have been ignored.

In the majority of cases, the experiments were set up by one of us and the observations made by the other alternately, the one observing having no knowledge of the cases studied.

EXPERIMENTS IN DETAIL

In the taurocholate, glycocholate, taurin and water experiments, the final result usually obtained was a precipitate, almost invariably flocculent in character; at times, light and diffused through the liquid; at other times, heavy and settled at the bottom of the tube. Sometimes both characters of precipitates were present.

The precipitates varied in amount from abundant to moderate or very slight in amount. In most cases the precipitates were tenacious, resisting ready diffusion throughout the liquid, but rising by a spiral movement and showing a marked tendency to remain in the center of the tube. No amount of agitation would cause these precipitates to dissolve. Other experiments showed a much finer precipitate which did not show the same tenacity and frequently would disappear on agitation.

[1] Marchild [illegible] of Alcoholic and Watery Extracts in th [illegible] philis, The Journal A. M. A., 1908, ii, 2140.

Owing to the character of the lecithin solution, which formed a cloudy emulsion, the observations had to be varied somewhat. The most characteristic change noted was a tendency to separation of the emulsion and central accumulation of the solid particles, while the fluid becomes clear. All stages could be noted from a perfect emulsion with uniform cloudiness to the formation of a dense, compact sediment and perfectly clear supernatant fluid.

From our observations we have come to the conclusion that with the taurocholate, glycocholate, taurin solution and the distilled water, a positive reaction consists of a light or heavy flocculent tenacious precipitate which does not dissolve on agitation; whereas we consider as positive a lecithin experiment in which the emulsion separates with the formation of dense central clumps and clear or almost clear supernatant fluid. A study of the cases in detail on this basis shows the following facts:

In the taurocholate tests, we found that the parasyphilitics gave the highest proportion of positive reactions, then the non-syphilitics, those with secondary syphilis and finally those with tertiary syphilis. It is possible that the proportion is highest in the parasyphilitics, because there was a slightly larger portion of these cases in which the serum showed some hemolysis or blood-tinging. We believe, however, that this is improbable, as all cases showing much tinging of the serum were rejected.

In the glycocholate experiments, again the parasyphilitics gave the highest proportion of positive reactions, then the non-syphilitics, the tertiary syphilitics, and finally the secondary syphilitic cases.

In the lecithin experimen[illegible] show more than twice as great a [illegible] reactions as any other series of cases; then come the cases of secondary syphilis; the non-syphilitics and finally the tertiary syphilitic cases gave no positive reactions. One of the non-syphilitic cases giving a typical reaction was a case of hypertrophic cirrhosis, in which the blood evidently contained bile salts. The patient was deeply jaundiced.

In this series, the number of positive reactions were too few to be of great value.

The results with taurin are somewhat better than with the other bile salts. Again, the parasyphilitic cases gave the highest proportion of positive results. The secondary syphilitic cases showed a slightly smaller proportion, then the tertiary syphilitic cases, and finally the non-syphilitic cases with about one-third as many positive reactions distributed equally between normal and other cases.

In the water experiments, we regret to state that, owing to inability to obtain the original of Klausner's article, we were not aware of his exact technic, but followed the same technic as in the other experiments, except in about a dozen cases in which we doubled the proportions of serum, making it correspond with the proportions used by Klausner. In the series in which this was done, the proportionate final results were practically identical, so that we feel that our methods will give the same results as the Klausner technic.

The results are as follows: The parasyphilitics again gave a very much higher proportion of positive tests. The secondary and tertiary syphilitics and the non-syphilitics gave an almost equal proportion of positive results, though in all the proportion was but about one-third of that in the parasyphilitic cases.

CONCLUSIONS

As a result of the foregoing observations, we are led to believe that none of these tests gives the practitioner a short road to the diagnosis of syphilis. They may be of some scientific interest, especially on account of the high proportion of positive results in parasyphilitics in each set of experiments, but the proportion of positive results in non-syphilitics is too high to make the test of value. Of the solutions used, taurin seems the best.

SERODIAGNOSIS OF SYPHILIS *

WILLIAM LITTERER, A.M., M.D.
NASHVILLE, TENN.

The scientific medical world is ever ready to herald any advancement in the refinement in diagnosis of this world disease, especially in view of the fact that there is probably no infection which at times offers greater difficulties in diagnosis than syphilis. It is true that the therapeutic test is valuable, but it falls far short of being a practical and scientific diagnostic measure. The confirmation from many workers as to the utility of the serum test seems now to have reached a stage where it can be used as an actual laboratory aid in diagnosis. In 1906 Wassermann, Neisser and Bruck[1] published a series of experiments demonstrating *in vitro* syphilitic antibodies in blood serum and specific material in syphilitic tissues. Later, Wassermann and Plaut[2] found syphilitic antibodies in the spinal fluid of 78 per cent. of 41 cases of progressive dementia.

This was the first application in clinical medicine and has ever since been known as the "Wassermann syphilitic reaction." Wassermann and others showed that in the serum of syphilitic apes a substance was produced which was not present in normal serum, and later they discovered that when the blood serum of syphilitic individuals was added to liver extracts of a luetic still-born the complement was anchored.

The researches of Bordet and Gengou in 1901 paved the way for this reaction, since the principle consists in the binding of the complement, a phenomenon first observed by these investigators on emulsions of bacteria.

It is a well-established fact that if the blood of an animal (A) should be injected every seven or eight days, for several inoculations into another of a different species (B), the serum of the latter will disintegrate the red blood corpuscles of the former, producing what is known as hemolysis. The dissolution of the red blood cells is dependent on two substances; neither can act without the other. One of these is always present in any blood serum, and is called the complement. It is thermolabile, i. e., its destruction occurs when heated to 58 C. for one-half hour. By heating, said serum is rendered "inactive"; hence the term "inactivated" is used when the complement is destroyed. The other substance necessary for hemolysis, known as an antibody or hemolytic amboceptor, results from the reaction of the injected animal against the injected blood cells. It is thermostable, i. e., it withstands heating to 58 C. There are vast numbers of antibodies. No two are identical. They are specific and are the reaction product formed in the blood of an animal when a given substance, toxic or otherwise, is injected into it. So all substances, which, when injected into animals, are capable of producing antibodies, are, in general, called "antigens." If typhoid bacilli were injected into a guinea-pig every seven or eight days for several weeks, there will appear in the guinea-pig's serum a substance that will dissolve typhoid bacilli. This substance contains two bodies: (1) complement and (2) bacteriolytic amboceptor or antibody, which is analogous to the substance produced by the injection of red corpuscles into an animal of another species, but differing materially in their antibodies. These substances contain identical complements which are always present in any animal. The antibodies are manufactured as the result of an introduction of an antigen (typhoid bacilli or red corpuscles); hence are specific. The serum from the typhoid guinea-pig will not dissolve the erythrocytes nor will the serum from the immunized animal with red cells disintegrate the *Bacillus typhosus.* Bordet and Gengou took advantage of the above facts to determine the nature of an infection by mixing the inactivated serum obtained from an animal suffering from some bacterial disease with the bacteria (antigen) producing the affection and then added complement (guinea-pig serum). The above mixture was allowed to stand for about three-quarters of an hour and then red blood corpuscles plus its hemolytic amboceptor or antibody were added. If no hemolysis occurred it was due to the fact that there had already been a binding of the complement, the antigen and bacterial amboceptor being homologous. Hemolysis would take place in case the serum contained no amboceptor against the bacterial emulsion, thus rendering the complement available for the hemolytic amboceptor. It is evident from the above reactions that it is possible to demonstrate not only antibodies in the serum containing them, but also the substance (antigen) that gives rise to their formation.

[2] Wassermann and Plaut: Deutsch. med. Wchnschr., 1906, No. 44.

Wassermann, Neisser and Bruck[3] applied the above principle to the demonstration of antibodies in the serum of persons suffering from syphilis. They employed for their antigen an alcoholic extract of syphilitic organs obtained from a luetic still-born. Marie and Levaditi found that a similar reaction, though a weaker one, could be produced with extracts from normal liver. Later, Michaelis, Fleischmann, Weil, Plaut, Volk and others showed that antigens for syphilitic serums were found in non-luetic organs. Landsteiner, Müller and Potzl[4] used extracts of guinea-pig heart as antigen, and found that their positive results coincided with the congenital luetic liver extract. This discovery is of great practical importance, as it will prove of inestimable advantage in promoting the availability of the Wassermann reaction, because the guinea-pig's heart can be secured with great readiness, while the congenital luetic organs are, at times, quite difficult to procure. Wassermann conceived the idea that these substances must be very similar to the lipoid bodies because of the solubility in alcohol of the active constituent from various organs. He directed Porges and Meier[5] to experiment with lecithin, and, in fact, found that the complement was anchored with syphilitic serums. Landsteiner and Müller discovered independently that lipoid substances, especially lecithin, produced this reaction. Potzl, Sachs and Altmann found that sodium oleate solution also acted similarly. Other substances, such as cholesterin, glycogen, sodium glycocholate and taurocholate, etc., were likewise found to react. Though Wassermann regarded this reaction at first as denoting the presence of antibodies in syphilitics and of antigens in luetic organ-extract, neither he nor his pupils in their later communications regard it in the sense of a recuperative reaction. Michaelis is of the opinion that "the Wassermann reaction does not reveal the presence of antibody against the cause of syphilis or its poisons, but some other substances which have no direct connection with the cause of syphilis, but which are found more abundantly in, or more easily extracted from, syphilitic organs than from normal ones." It is readily apparent that the lipoid element in this reaction does not depreciate its value; on the contrary, it may explain the lipoid degeneration in parasyphilitic diseases. The diagnostic value of the reaction in several thousand cases examined by the best authorities surely establishes it of distinct value, despite laboratory criticisms concerning its actual scientific foundation. In performing my tests I have employed only a few times the lipoid bodies, as lecithin, cholesterin, etc., preferring to use guinea-pig heart extract in the reaction with luetic serums.

The substances employed in the Wassermann reaction briefly[6] stated are as follows: (1) blood serum of suspected luetic (inactivated); (2) organ extract (luetic liver or guinea-pig heart macerated, extracted with alcohol and inactivated); (3) complement (guinea-pig serum, not inactivated); (4) washed sheep's blood corpuscles—sheep's blood defibrinated and washed with normal salt solution about three times, and, finally, put up in 5 per cent. and 50 per cent. strength with normal salt solution, used for dilution; (5) hemolytic serum obtained by injecting a 5 per cent. sheep's blood corpuscles into a rabbit every eight or ten days, for about four or five times; about ten days after the last injection blood is removed from heart and serum collected and inactivated.

It is absolutely imperative that, before the actual performance of the reaction, all material to be used should be tested (1) to standardize the amboceptor, (2) to see that extract does not alone anchor the complement or hemolyze the sheep's corpuscles, (3) to see that the complement is active.

In every test it is necessary to employ a few known syphilitic and as many normal serums to serve as controls for the suspecter sera. Sometimes uncertainties arise in determining the result of the reaction, but in practically every instance it is traceable to failures of sufficient controls and the proper use of materials. In doubtful reactions, a second or third test should be estimated with careful controls and using different antigens. It is not necessary to explain in detail the entire reaction, especially since there have been so many excellent articles of late written on the subject. The carrying out of this reaction, as it should be conducted, unfortunately is attended with difficulties which may discourage many who undertake it. There is no question but that a modification of the method that will furnish us an easy and accurate diagnosis is very much to be sought for. Many investigators have attempted to simplify the method, but thus far no great step has been successfully accomplished toward this end until quite recently.

Noguchi[7] describes a simplification of this test so sweeping that it practically eliminates all the technical difficulties and places it within the reach of any well-trained laboratory man. His new method is based on the same principle as Wassermann's and utilizes the Bordet-Gengou phenomenon of complement-fixation to determine the presence of syphilitic antibody in a given specimen of blood serum or cerebrospinal fluid. It is quite different from the Wassermann method, in that an antihuman hemolytic system instead of antisheep hemolytic system is used. The original Wassermann method is subject to an error arising from a varying amount of natural amboceptor found in human serum, which is capable of being reactivated by guinea-pig's complement. The Noguchi modification eliminates this source of error, since it enables one to detect the presence of even a fractional part of one unit of syphilitic antibody in a given specimen. There are two different ways of applying the test: "In one, the reagents are employed in liquid form, and in the other they are used in a dried state on filter-paper." This latter way is accomplished by saturating filter-paper, when in solution, with (1) antihuman hemolytic amboceptor; (2) the guinea-pig complement; (3) antigen (organ extract). The papers are dried and standardized.

[5] Porges and Meier: Berl. klin Wchnschr., 1907, No. 44.

[6] A more detailed account of the technic of the reaction will be found in a most excellent article by Butler: The Journal A. M. A., Sept. 6, 1908, li, 824.

[7] Noguchi: Jour. Exper. Med., March 1, 1909.

For further details Noguchi's original article[7] may be consulted. I have employed this method about fifteen times, using the reagents in liquid form.

There were a few minor points that Noguchi did not make entirely clear, but, on the whole, I had no difficulty in following it. From the little experience that I have had with the test, I can in the main confirm Noguchi's contentions with reference to the simplicity as well as to the delicacy of the test as compared with the original Wassermann. There were seven cases (of male negroes) in which doubtful reactions were obtained by the original Wassermann reaction. The modified method showed that these seven gave very positive reactions. In two cases very positive reactions were obtained, in which no history of syphilis, either acquired or congenital, could be obtained; the subjects were perfectly healthy, and their physical examination resulted negatively. The original method was negative in both cases. It is barely possible that such a test is too delicate; many more tests are necessary, however, in order to decide such a question. I have used the much simpler precipitate tests with lecithin, sodium glycocholate, taurine and other bile salts and shall discuss them in detail in another article. The precipitate tests are not considered as reliable as the Wassermann reaction. They are based on entirely different principles. The bulk of my work in the last twelve months has been with the original Wassermann reaction. They are as follows:

REPORT OF REACTIONS

Forty-six presumably healthy white men, giving no history of syphilis, were examined by the original Wassermann method. All the reactions were negative, save two which were recorded as doubtful; subsequent tests, using different antigens, still showed doubtful reaction.

1. The first case showing this doubtful test was that of a man aged 24, height 5 feet 10 inches, weight 160 pounds. He had all of the diseases incident to childhood; contracted typhoid fever at the age of 15, and smallpox at 19; he was otherwise healthy all of his life. He denied all venereal diseases. No glandular involvement or scars on genitalia or elsewhere could be discerned. He had never had sore throat. Hereditary syphilis could not be absolutely excluded.

2. The second patient, in whom a doubtful reaction was recorded, was a man, aged 20, height 5 feet 8 inches, weight 145 pounds. He had all of the diseases of childhood save pertussis; at 18 years contracted lobar pneumonia, from which he was several months in recovering. Since then he had been in excellent health. He had gonorrhea twice, but denied lues. There was no glandular involvement in any part of the body; no discernible scars on genitalia; no history of sore throat or eruptions on body. His father contracted syphilis when 19 and married at 21, only taking six months of antiluetic treatment.

Of the forty-six apparently healthy, colored male adults giving no history of syphilis, and having no scars on their genitalia or elsewhere, five gave a positive Wassermann reaction and ten gave doubtful reactions. There were two groups of the forty-six cases that were examined. The first group consisted of twenty-five negroes who lived in the country. The second group, numbering twenty-one, represented the city negro. Of the country negroes only one showed the positive Wassermann, and three the doubtful reactions. In the three cases which were doubtful by the original Wassermann, the Noguchi modification proved distinctly positive. All of these cases showed glandular involvement. In these cases I was unable to exclude hereditary syphilis. In the city negroes, numbering 21, 4 showed the positive Wassermann, while 7 gave doubtful results. The Noguchi modification proved to be positive in all seven of the doubtful cases. All of these negroes claimed to be perfectly healthy and denied any syphilitic trouble. No scars on their genitalia could be discerned. There was no history of sore throat or body eruptions. In the 4 positive cases and in 5 out of the 7 doubtful ones there was slight enlargement of the lymph nodes. The remaining two subjects were perfectly normal. Congenital syphilis could not be excluded in any of these cases.

It is evident from the above that a good percentage of the city negroes have syphilis, either acquired or congenital, and do not know it, or else their statements could not be depended on concerning this affection. In the country negro, this disease is comparatively rare as compared to the city negro.

Out of 58 non-luetic cases of various diseases, I obtained a positive reaction in two cases of advanced carcinoma, one of advanced sarcoma and one of hydrophobia, and one of profound malaria (estivoautumnal). The following is a detailed report showing the various diseases in which the reaction was tried:

3 cases	scarlet fever	negative reaction
8 cases	lobar pneumonia	negative reaction
5 cases	typhoid fever	negative reaction
3 cases	advanced tuberculosis	negative reaction
4 cases	moderate tuberculosis	negative reaction
5 cases	incipient tuberculosis	negative reaction
2 cases	advanced carcinoma	positive reaction
3 cases	malaria tertian	negative reaction
2 cases	lupus	negative reaction
2 cases	carcinoma	negative reaction
2 cases	sarcoma	negative reaction
1 case	advanced sarcoma	positive reaction
1 case	amebic dysentery	negative reaction
1 case	tetanus	negative reaction
2 cases	diphtheria	negative reaction
1 case	hydrophobia	positive reaction
2 cases	acute nephritis	negative reaction
4 cases	chronic nephritis	negative reaction
2 cases	furunculosis	negative reaction
2 cases	abscess	negative reaction
2 cases	infected gall bladder	negative reaction
1 case	malaria (estivoautumnal)	positive reaction

These cases were obtained from the Nashville City Hospital, the Vanderbilt Medical Hospital, and a few from private patients of physicians. The two carcinoma cases that gave positive reactions show the following history:

The first patient, a white woman, married, aged 57, mother of three children, had had the diseases incident to childhood; denied all venereal trouble. There was no glandular involvement or throat trouble, and no eruption on skin. One year and a half ago, a diagnosis of carcinoma of cervix was made by microscope. She is now in the last stages of carcinomatous disease. Recently her blood was withdrawn and a Wassermann reaction resulted positively.

The second patient, a white woman, married, aged 50, mother of two children, also denied all venereal trouble. There was no glandular involvement or throat trouble; no history of rash on body. The patient had pneumonia when about 22, and when about 40 years old contracted grip. She noticed a tumor in her breast two years ago, which was removed and pronounced to be carcinoma on microscopic examination. Recurrence resulted and a second operation was performed. The patient is now in the last stages of this disease, and her blood has shown on three different occasions a positive Wassermann reaction.

The third case is one of advanced sarcoma, occurring in a white man, aged 26, who had always been healthy, save for the diseases of childhood. He denied all venereal trouble. There was no glandular involvment or history of sore throat, or skin eruption. About one year ago the patient noticed a small tumor, size of hazel-nut, on inner aspect of leg. The tumor was examined by microscope, which showed sarcoma. Amputation advised but patient refused. Several months later a general sarcomatosis developed. The Wassermann reaction was positive two different times.

The fourth case was that of hydrophobia occurring in a married white man, aged 35, who had always been healthy. He denied syphilis, but said that he had had gonorrhea. He was bitten on the hand by a rabid dog; three months later developed typical symptoms of hydrophobia. After his death, I obtained sufficient amount of blood for the Wassermann test, which was positive. The case was proved to be hydrophobia by the finding of the Negri bodies in the brain, and by the inoculation test.

The fifth case was one of malaria (estivoautumnal) occurring in a white married man, aged 27, who contracted pneumonia when 18 and at 24 had a severe attack of grip. He denied syphilis, but had had gonorrhea. For the past twelve years he had malaria. When the blood was obtained, the patient was suffering from a profound attack of estivo-autumnal type of malarial poisoning, from which the patient died in two days. The Wassermann reaction was positive.

In 88 per cent. of 80 cases of active syphilis, primary and secondary, the reaction was found positive. The comparatively low positive results are due, perhaps, to the fact that three patients who gave negative reactions had received antisyphilitic treatment at the time the test was made.

I conclude by stating that more than 90 per cent. of cases of active syphilis give the reaction. The occasional reaction in other diseases lessens the diagnostic value of the test very little, if at all. The Noguchi modification is apparently more delicate than the original Wassermann. I am of the opinion that a good percentage of the city negroes of the south giving negative syphilitic histories will show a positive Wassermann reaction as modified by Noguchi, since many have hereditary syphilis.

Fifth Avenue and Elm Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. NOGUCHI, WIEDER AND L'ENGLE AND LITTERER

Dr. Maximilian Herzog, Chicago: The serodiagnosis of syphilis has certainly assumed great importance from the standpoint of the clinician. Many thousands of tests are reported from Europe, four clinics there alone reporting investigations in over 10,000 cases. What we know concerning the clinical importance of that test is based on the original Wassermann test. The modifications of this test proposed have all been shown to be defective. Dr. Noguchi referred to some remarks I made in another section when I stated I had tried the Bauer modification and had finally given it up. I did so on account of the great variability of the amboceptor-content in human serum. On the average, in a majority of cases, this variability is not so great; but there are some cases which show an enormous amount of hemolytic amboceptor, and some with none at all.

Some of the objections to Dr. Noguchi's modification that I consider valid are the following: He uses several of the substances necessary in a dry state and gives rules by which to prepare them in such a dry condition. Now, he has made the point that in his test all the quantities are known; yet I have seen in his article in the *Münchner med. Wochenschrift* the statement that non-heated human serum frequently has an anti-complemental effect as to the guinea-pig's serum complement. If, therefore, you have such a serum and have made the test, you have no hemolysis and you do not know where you stand. Dr. Noguchi's reply to this objection is that you must reduce the amount of human serum; but in this he disregards his own principle, which says that the test must be made with absolutely equal quantities. Hence, I think that it will finally be found that his test has serious defects, as have other modifications of the Wassermann test. I do not want to decry Dr. Noguchi's excellent work; but I wish to say that when we are using the serodiagnosis of syphilis for the benefit of the clinician we ought to stick, for the time being, at least, to the Wassermann test. The point that I urge against Noguchi's modification is that it will go out into the hands of the general practitioner, and everyone will believe that he can handle the serodiagnosis of syphilis. We shall then get unreliable results, and the serodiagnosis of syphilis will be discredited among practitioners. The test should be made by men with good laboratory training, who know all about the principles of hemolysis, who can meet defects and abnormalities when they do show themselves, and who are not merely going through a mechanical routine with test papers.

Dr. Frank Smithies, Ann Arbor: Without wishing to detract in the least from the ingenious device of Dr. Noguchi, I feel that I must endorse the remarks of Dr. Herzog. The commercialization and improper working of these tests by untrained persons frequently casts a good deal of doubt on the value of such a test in the minds of practitioners and the laity in general, so that I think that the work should be performed exclusively by expert laboratory men. We must admit that Dr. Noguchi has himself laid stress on this very point. My own work in connection with Dr. Cummings in 199 cases showed that 89 per cent. of known syphilitics gave positive reactions by the original Wassermann procedure; yet this reaction was obtained in other diseases. We have had it positive in pernicious anemia, cancer, Addison's disease, early measles, and tuberculosis, and in many patients who had received treatment for rabies according to the Pasteur method. We have attempted to give an explanation of its occurrence in the rabies cases in a recent preliminary report in The Journal, April 24, 1909, pp. 1330-1331. It appears to me, therefore, that while we do get a certain amount of clinical information by the Wassermann and the Noguchi tests, it is impossible, as Dr. Herzog has insisted in the present condition of our knowledge concerning the subject to entrust the work to any but experienced laboratory men.

Dr. William J. Butler, Chicago: I have investigated the precipitate reactions in conjunction with Dr. Mefford. With reference to the taurocholate and glycocholate of sodium on which we have already presented our results, we found the glycocholate of sodium conducted itself pretty well toward various sera; and while I do not wish to be put on record as believing that it is of decisive value in the diagnosis of syphilis, I think that it is not to be discredited. It gives closer information concerning the syphilis question than does any precipitate reaction, and its results parallel more or less those of the Wassermann reaction. Regarding taurin, my experience is limited. I tried it in ten cases of tuberculosis, which constitutes a good class of cases to try these reactions in. In none of the eight cases in which a positive result was obtained had we reason to suspect syphilis, so we stopped using it. Regarding the Wassermann reaction and its being found positive in other infections than syphilis, as reported by Dr. Litterer, we have all had experience in finding the reaction in other infections; and I think there are two reasons why this is so: First, there are so many sources of error in performing the reaction, that unless we adhere to pretty close lines, we are bound to fall into the mistake of making false interpretations. If we adhere to the original idea that a positive reaction is to be concluded only from a complete or almost complete inhibition of hemolysis, we shall seldom fall into error. The cases formerly termed 1 + or 2 + are gradually, in the hands of most investigators, being discarded; because there are too many sources of error in attempting to draw the lines between a 1 + and 2 + and a negative reaction. The experiments should be repeated and repeated, and the controls must come out perfect before such deductions can be made. Second, when a strong reaction is obtained, close inquiry invariably reveals a history of syphilis. The reaction is found in leprosy, occasionally in scarlet fever and noma. The point to which Dr. Herzog directs attention, namely, that human serum alone may act as an antihemolytic has, of course, been a matter of observation from the beginning of this work, and will not be eliminated by any of the modifications of the reaction that have been offered. While the modifications of Tschernogubow and Noguchi will eliminate the natural amboceptor for sheep's corpuscles, this is practically *nil* in all syphilitic serum so far as it interferes with the reaction, and on this point rests the modification advanced by Bauer.

Dr. J. J. Kinyoun, Washington, D. C.: I agree with Dr. Herzog that the Wassermann reaction should be done in the laboratory by trained men and not for the time at least be given over to the clinician. I have no fear that there will be any material departure from the methods now in vogue and it will be a long time before the clinician will undertake to do the test even if it were more simple than the modifications now proposed by Dr. Noguchi. To illustrate this point: As is well-known, a simplification of the Widal test for typhoid was made by von Ficker, which was intended to put this in the hands of the clinician, yet despite its simplicity and availability for a bedside test it has not been received with favor for practitioners. Moreover the number of requests on the laboratories where the Widal test is made has increased. Now I believe that the same will obtain for the Noguchi method, and that but few clinicians will undertake to do the test, the majority will depend on the laboratories as at present. On the whole, my observation shows the Noguchi method more delicate than the original, and sometimes I am led to believe that it is a little too delicate.

Dr. H. Noguchi, New York City: In carrying out the serodiagnosis of syphilis by complement fixation the antigen plays the most important rôle in the results. Not only the quality of the antigen should be suitable, but also the dosage of a suitable antigen should be carefully selected. An excess of antigen is to be avoided because of rendering the test unduly sensitive. Certain investigators who obtained a high percentage of positive reaction with scarlet fever or other non-syphilitic diseases (except leprosy) by using the Wassermann *method now admit that they employed unsuitable antigen* or an excess of this reagent. Should any one happen to get unduly sensitive reactions with any method he ought to reduce the dose of antigen to eliminate oversensitiveness. No one should adhere without certain trials to every dose of each reagent prescribed as the reagents may differ somewhat with the course, but he should understand the prinicples of the test and adjust the dosage according to the circumstances. The reading of the reaction is another important factor in deciding the results. It is my rule to base the diagnosis of syphilis on unmistakably strong reactions only, but never on weak reactions when the clinical diagnosis is unknown. On the other hand, I take even a faint positive reaction as a sign of active syphilitic process still present when the specimen is derived from a known luetic case. Again, for the purpose of excluding possibility of syphilis from a case I put value even on a faint reaction, no matter whether the person may seem apparently healthy or not. Thus, according to my opinion, the reactions may be utilized for three different purposes, namely, when strongly positive as a diagnostic; when weakly positive as a sign of still existing syphilitic foci in a luetic subject, and as a means of excluding syphilitic suspicion from a person. For the two last purposes there can be no objection to a very sensitive method, and, in fact, for selecting wet-nurses, recruiting for the military or naval services, choosing a donor of blood for transfusion, etc., a system which will not miss the reaction whenever there is one should be recommended. This is my answer to Dr. Litterer's reports. In regard to Dr. Herzog's question I may say that it is rare to meet with specimens containing disturbing quantity of anticomplement. If such a case should occur the anticomplement can be removed easily either by reducing the serum to be tested or by increasing the quantity of complement. My system is perfectly adjustable as each factor is separate and titratable.

Dr. Henry S. Wieder, Philadelphia: I have only to say that the fact that none of the tests are any good is shown by the fact that Dr. Butler obtained the best results from glycocholates, while we got the worst results with them. The reactions depend more on the idiosyncrasy of the patient than on the disease. In tuberculosis Butler got 8 out of 10 positive reactions depend more on the idiosyncrasy of the patient than with taurin than with anything else. The result depends on the people you encounter. I do not believe that the disease has much to do with it.

PRIMITIVE GRAPHIC SIGNS IN PULMONARY WORK

BASED ON PHONETIC VALUES

JOSEPH H. BARACH, M.D.
PITTSBURG, PA.

A thing is practical in proportion to the extent of its application. Up to the present time have the graphic expressions used to denote physical signs in pulmonary cases proved to be really practical? If not, why not? That they have not been applied as extensively as they should be is conspicuously seen whenever one attends clinics and visits hospital wards. And the reason for this is largely because of the un-meaningness of many of the proposed signs.

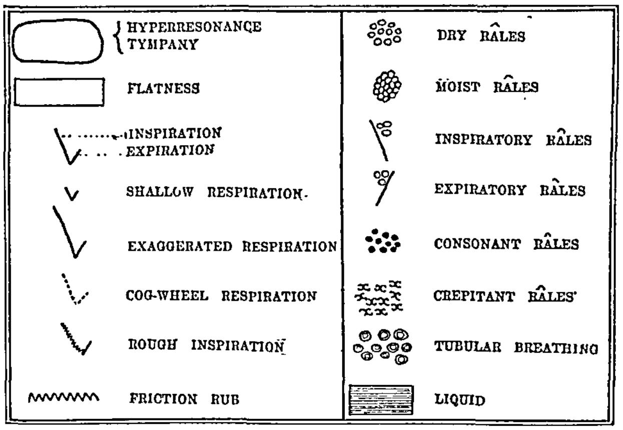

Fig. 1.—Primitive graphic signs.

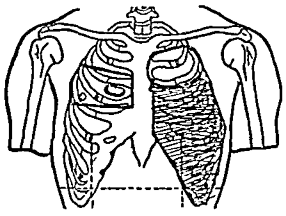

Fig. 2.—Percussion signs right side: Area of dulness enclosing area of resonance, i. e., cavity; left side: area of tympany overlying liquid.

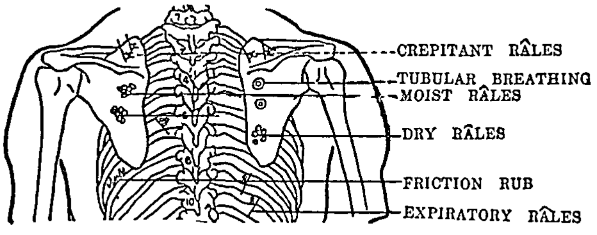

Fig. 3.—Auscultation signs.

At various clinics there have been adopted individual modifications, and in the invention of these signs the basic principle that should underlie such a system has not been sufficiently considered. The result has been that many of the signs are fanciful in proportion to the skill of their authors, and often indeed are fair representation of art for art's sake.

Unless signs are of the simplest character and have a distinct meaning of themselves they are difficult to memorize and retain. The average man on reading over a series of signs in a text-book will, within five minutes, remember but one or two out of the twenty or more; so that if he is to use them in his work he must "learn a new language." Therein lies the reason for the limited scope of their adoption.

Tyler enumerates five ways by which men communicate with each other. One of these is written signs. He says, "Signs, to be understood, must be of the natural self-expressive sort." A sign may be an imitation of the object desired to designate, or a symbol of the same; in either case its association should be readily understood. For our needs their association should be so thoroughly familiar that conscious memory should play no part in their usage. They should belong to the "unconscious memory." (Spencer.)

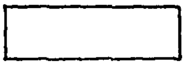
By the Chinese, and more so by the Japanese, along with the signs which originally were pictures, certain other signs are used to present sounds in their written language. With characters to express phonetic values, it is easily seen that a complete system would naturally develop as a part of such a written language. This can not be done in our writing. We may, however, adopt a system of symbols of the simplest primitive sort that is capable of entirely fulfilling the purpose for which graphic signs are intended in pulmonary work. In such a system each mark should express something definite. To this end I have carefully considered the signs that up to the present have been in use, retaining those which are true and capable by themselves of transferring a meaning to the reader of them and replacing others by new elemental signs which express the meaning intended to convey.

The first requisite for the record is a chest outline that is accurately proportioned. At the hospital we use an outline 3½x4½ inches on the history blanks, and in my private work I use the same size rubber stamp on a 4½x8 card.

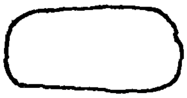
PERCUSSION SIGNS

Normal Resonance.—If the percussion sounds seem normal, there is no need for making any marks at all.

Flatness or Dulness is designated by drawing straight border lines over the limits of the involved area. The straight lines, when joined in the shape of a square or oblong, or irregular area, always suggest to the mind a block or something flat or solid.



Tympany or Hyperresonance may be shown by a curved outline over the involved area. Round outlines suggest to the mind hollowness and hollow sounds.



These are the basic signs for percussion.

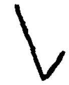
The degree of *flatness* or *hollowness* may be specified in the history or by abbreviation. In combination on chest outlines they are most suggestive. For example —an oval outline included within a square one at once suggests a hollow space in a solid body, a cavity in a solidified lung. Within these round or straight border lines can be marked the evidences of auscultation.

AUSCULTATION SIGNS

Inspiration is well represented by the down stroke of the letter V, the air rushing downward into the lung.

Expiration is shown by the up stroke, the air rushing upward out of the lung.

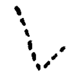
Relative Values of the sounds normally heard over the chest with *inspiration* and *expiration* are represented by a longer downward and inward stroke (inspiration) and a shorter outward and upward stroke (about one-fourth the length) for expiration. As with the resonance, normal values need not be expressed.



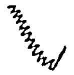
Abnormally Prolonged Expiration or Inspiration is represented by the relative increase in the length of either of the lines.

Shallow Breathing is represented by small marking.

Cog Wheel Breathing is pictured by interrupted lines.



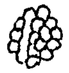
Roughness of expiratory sounds is plainly indicated by a serrated line (inspiratory in similar manner).



Dry Râles.—On listening carefully to chest one is impressed with the fact that dry râles seem as discrete, individual sounds. I would, therefore, represent them as discrete circles.

They may be large or small, or both, in proportion to their fineness or coarseness or mixture of both.

Moist Râles, on the other hand, always seem to be confluent sounds running together, as bubbles do. I would, therefore, represent them as circles joined—large or small, or both, as the physical findings suggest.

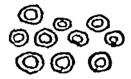


Inspiratory Râles.—These should be designated by marking the circles along the inward stroke.

If heard at the beginning of inspiration, then at the beginning of the line; if at the end, then at the end of the line.

Expiratory Râles are designated by placing the signs at the beginning or middle or end of the outward line, corresponding, according to the judgment of the examiner, to the beginning or end of the expiratory sound.

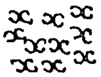
Tubular Breathing is designated by the image of a tube, a circle including a circle, a sign that is perfectly easy to make. It represents the bronchus; it suggests how tubular breathing is produced; seen on a diagram, it is an object-lesson in itself. If it is to represent the bronchial breathing of a small bronchus, the sign is a small one; if a large bronchus, the sign is made larger. The location also suggests its possible size.



Mixed Sounds, as, for instance, when the ear detects bronchial breathing, and, at the same time moist or dry râles, are shown by the sign of each recorded side by side. This is more accurate than to have a combination sign for both; for, accurately speaking, these sounds are produced by adjacent parts of the lung and never from one spot.

Friction Rub is very well represented by the sign frequently used which represents a saw edge, or jagged rough surface. Fine or coarse sounds are easily suggested by the size of the irregular up and down stroke. The location of the sign will designate its pleuritic or pericardial origin.

Crepitant Râle.—This sound is so important and usually of such distinctive meaning as to deserve a sign of its own.



The sign that is here shown represents the separation of the approximated alveolar walls, the manner in which we believe it is produced by the inspired air. One may also see in it the letter *c* for crepitant. This sign should accompany the inward or outward line, designating the time at which it is heard.

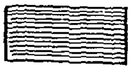
When it can be determined that the sound is produced by a fine pleural rub, then it should be represented by the friction sign. We already have a sign for the so-called *subcrepitant râle* that is merely a fine moist râle—and it would be well if the term itself were abolished, as its meaning is frequently confused (Bonney).

Consonance is a quality that râles possess under certain pathologic condition of the tissues out of which they emanate. This quality being largely that of increased intensity, is very well represented by having the sign of the râles appear as black dots, which convey a distinct meaning as contrasted with the circles.

The dots are discrete or confluent, according as to whether the râles seem dry or moist. A large element of personal equation enters into the interpretation of sounds possessing consonance, and, all considered, a dubious value is placed on their reliability for diagnostic inference.

The foregoing signs, if carefully considered, will each be found to correspond very closely to the underlying principle of phonetic writing, in which the picture or sign in this instance, should represent the character of the sound to be designated. Their meaning is therefore true.

Liquid is represented by a series of horizontal lines included within straight boundary lines. The outlined area is flat and, auscultatory sounds being absent, may be effaced by the horizontal lines; these also represent liquid better than any other simple sign.



This system includes the desirable elements of the various former systems of signs and in the new *ones* offers to the mind the simplest primitive forms in such a way as, once they are considered, they should be naturally retained.

4502 Fifth Avenue.

Headache Remedies.—Remedies for the relief of migraine are almost without number, but the most that can be expected of any of them is a diminution of the severity and a curtailment of the duration of the pain once the attack has become fairly established.

THE COMING REVISION OF THE UNITED STATES PHARMACOPEIA

TORALD SOLLMANN, M.D.
CLEVELAND, OHIO

The decennial convention for the revision of the Pharmacopeia will meet in Washington, D. C., on the 10th of May, 1910. The intervening time is none too long for the careful consideration of the policies which the delegates to this convention will have to determine. Their decisions will be the main factor in the fate of our Pharmacopeia, at least for the next ten years, and perhaps for much longer. The times are peculiarly favorable for effecting any necessary reforms, and it may be many years before an equally favorable opportunity will again present itself.

This convention elects the revision committee and the officers and trustees. It may also direct the scope of the Pharmacopeia and the general methods to be used in the revision. Within very wide limits, it has the power of prescribing almost any policies which it considers wise. It is, therefore, charged with very great responsibilities which should not be undertaken without serious thought and reflection. According to the constitution this responsibility is divided between the two professions of medicine and pharmacy. The constitution permits of more medical than pharmaceutical delegates, and thereby imposes the greater responsibility on the physicians. Most unfortunately, our profession has shirked its share in recent years and has turned the work over to the pharmacists. The latter have discharged their duties in a manner which should be a model to us. Accordingly we have in the Pharmacopeia a work which is a fairly representative standard of the best in modern pharmacy; but which is seriously lacking as a standard of the best in modern pharmacotherapeutics. The revision has passed into the hands of the pharmacists, because they were willing to do the work which we shirked. They merit praise, rather than reproach, for "capturing the Pharmacopeia."

AS TO ITS CAPTURE

Another reason for this capture is that the technical work of the revision requires mainly pharmaceutical rather than medical knowledge. Because of this fact it would be disadvantageous to increase materially the medical representation on the general revision committee, or to elect a clinician as editor. On the other hand, physicians should have at least an equal share in directing the general policies, and they alone should decide what substances are to be admitted to the Pharmacopeia. This is absolutely indispensable—at least, if the Pharmacopeia is to be a medical standard and not merely a compilation of pharmaceutical receipts and tests. If the latter is to be its main function, the wisest course for the medical profession would be to abandon a false position and to disclaim all responsibility. The founders of the Pharmacopeia certainly did not have this pharmaceutical conception of its scope, for in the early days the Pharmacopeia was published by the medical profession exclusively. With the discriminative evolution of the two professions, it became a wise step to place the technical matters in pharmaceutical hands. On the contrary, the simultaneous and unnecessary abandonment of a controlling voice in the direction of the general policies, and especially of the admissions, was distinctly a step in the wrong direction.

In theory we still retain this control, and it may not be too late to make it practically effective. The constitution provides for equal representation for both professions, so far as national and state bodies are concerned. It also provides that each college of pharmacy and of medicine is entitled to send three delegates. Since there are more medical than pharmaceutical schools, it was the obvious intention of this provision that the medicine should have the larger representation. This, however, is not the way in which it would work in practice. The Pharmacopeia is the "book of books" in pharmacy, with every detail of which every competent pharmacist must be thoroughly familiar, however little he may know besides. Accordingly every member of a pharmaceutical faculty would be prepared to take an intelligent interest in the revision. The case is very different with the physician. For him the Pharmacopeia is only one book, if an important one, among many others which he must study. The acquaintance of the ordinary physician with the Pharmacopeia cannot, therefore, be as intimate as that of the pharmacist. Accordingly only a small proportion of a medical faculty, as a rule, would be prepared to understand the details of the revision. While, therefore, it should be easy for every pharmaceutical school to send its contingent of delegates, it would be difficult for many medical schools to find on their faculties three men who would be willing and able to attend. This inequality could be easily remedied by reducing the number of delegates for both professions—a reform which may be supported by other weighty arguments. There is little doubt that the present size of the convention is entirely too large for the most effective transaction of its business in the brief time at its disposal.

A VICIOUS CIRCLE

After all, however, the main reason why the policy of the Pharmacopeia has passed out of the hands of the medical profession is that the latter has not exerted itself to retain the control. This, again, is due mainly to the fact that the Pharmacopeia has become so predominantly pharmaceutical in its tone and contents that it is really of minor importance to the physician. There is here a vicious circle: Physicians take no interest in pharmacopeial revision, because the Pharmacopeia does not represent their vital interests; and the Pharmacopeia does not represent their interest because they take no interest in its revision.

Let us face the issue frankly: If the Pharmacopeia is not and cannot be made practically important to the physician, then let us abandon it altogether. If it is or can be made important, then let us live up to our responsibility, break this vicious circle, and start it to revolve in the useful direction of improvement. Few will deny that the Pharmacopeia has within it the germ of the greatest practical usefulness—were it only as an instrument in putting down the evils of nostrum-quackery. In fact, the Pharmacopeia is one of the strongest potential factors in advancing scientific therapeutics—which means simple and accurate prescribing.

So far as I have been able to ascertain, the medical profession is practically a unit in believing that some radical changes are required to make this potentiality an actuality—however widely opinions differ as to the details of these changes. These differences of opinion are a most healthy symptom, for from their thorough discussion we may expect the nearest approach to perfection. It is essential, however, that the bulk of this discussion should take place before the convention meets. At the convention the time for discussion will be altogether too limited to hope for the best results. It is also essential that the delegates should be well informed and, so far as may be, united. For, while the times are propitious, we dare only hope for the best results if those who believe in the necessity of reform will present a united front. Finally, it will be necessary that the program of reform should not be vague and indefinite, but that it be presented in the form of clean-cut motions.

With this object in view—namely, of submitting a definite program for discussion—I venture to recapitulate, in the form of motions, the principles of reform which I had the honor of discussing before the Section on Pharmacology and Therapeutics at the Chicago meeting in 1908. I would refer those who are interested in the arguments to the published paper.[1]

PRINCIPLES OF REFORM

The changes which appear to me as of the first importance, from the medical standpoint, are about as follows:

A. *Reorganization of the Revision Committee.*—The complexion of the revision committee should be changed so that the present relatively large committee, with vague individual responsibilities, may be replaced by a smaller "executive committee," each member being elected directly by the convention as chairman of a given department of the revision, and thus charged directly with the full responsibility for his department. The departments are enumerated under Motion 3. Their personnel, in addition to their chairman, should consist of "associate members," whose number, selection and appointment should rest with the chairman of the department, with confirmation by the executive committee. The appointment of all the members of the admission committee, however, should be made directly by the convention. The chairman of the editorial committee should be *ex officio* chairman of the executive committee. The appointment of all the members, associate as well as executive, should be conditioned on effective work, and in case of failure should be subject to revocation by the board of trustees.

Unfortunately the election of the revision committee precedes the discussion of amendments, in the order of business of the convention. This would mean, as I interpret it, that any reforms along these lines could not be made fully effective until the next convention, in ten years—unless, indeed, the newly elected revision committee would offer the self-sacrifice of resigning in a body when such amendments are adopted. This would be by far the simplest solution of the difficulty. Otherwise the convention would need to provide a temporary makeshift by filling all the newly created positions from the revision committee which had been elected according to the old plan. This would be feasible, although more complicated.

These changes are covered by the following motions:

Motion 1.—That Article I of Chapter V (page 13[2]) of the by-laws be amended to read as follows:

"The committee of revision shall consist of (a) an executive committee, composed of the chairmen of the ten departments of revision, to be elected at the decennial meeting; (b) the associate members to be appointed by the chairman of each department with the approval of the 'executive committee' (except that the members of the 'admission committee' are to be elected directly by the convention as provided below under Article IV; (c) the president of the convention, *ex officio*.

---

[1] The Journal, Dec. 12, 1908, pp. 2013-2018.

[2] The "pages" refer to the pamphlet "United States Pharmacopeial Convention," printed by order of the Board of Trustees, Washington, D. C., 1909.

"The business of the committee may be transacted by correspondence."

Motion 2.—(Required only if a revision committee has already been elected according to the old plan). That, as a temporary expedient, the chairmen of the departments for the current revision be elected from the members of the revision committee, elected according to the by-laws hitherto in force.

Motion 3.—That Article III of Chapter V (page 14) of the by-laws be amended to read as follows:

"The departments of the Revision Committee shall be the following: (1) Editorial; (2) Admission; (3) Pharmacognosy and Botany; (4) Proximate Principles and their Chemical Assays; (5) Volatile and Fixed Oils and Resins; (6) Inorganic Chemicals, Chemical Processes and Reagents; (7) Organic Chemicals (including Synthetic Products); (8) Pharmaceutical Processes and Recipes; (9) Pharmacodynamics (including Sera and Physiological Assays); (10) Therapeutics (including Strengths and Doses)."

"The chairman of the editorial department shall be *ex officio* chairman of the executive committee. He shall have the general direction of the work of revision, assign the subjects to the departments, receive and announce the votes of the executive committee, attend to the correspondence and prepare the final manuscript. It shall be his duty to present to the decennial meeting a report of the work of the revision committee. The executive committee shall elect from its members two vice-chairmen and a secretary to serve until their successors are elected."

B. *Control of the Admissions.*—This reform is of most particular interest to physicians. The present method rests on the entirely indefensible assumption that the chemist and pharmacist are the most competent judges of therapeutic usefulness. This absurd arrangement should be abolished by placing the control of admissions in a special committee elected for their special fitness for this particular purpose—by far the most delicate and complex problem with which the revision will have to deal.

Motion 4.—That Article IV (page 14) be amended to read as follows:

"The Convention shall elect the entire committee on admissions, which shall consist of a chairman and five other members, of whom at least four shall be physicians. It shall be the duty of this committee to pass on the admission of substances to the pharmacopeia, subject to any general direction which the convention may give, and to report their conclusions promptly to the chairman of the 'executive committee.'"

Motion 5.—That Article V (page 14) be replaced by the following:

"The chairmen and other members of the revision committee shall receive such compensation for their services as the board of trustees may direct. Vacancies may be filled by election by ballot by the executive committee."

C. *Nominating Committee.*—These changes will necessitate some alterations in the method of nomination:

Motion 6.—That Chapter VI of the by-laws (page 14) be replaced by:

"*Article I.*—A nominating committee of ten shall be elected by and from the delegates present at the decennial meeeting.

"*Article II.*—The nominating committee shall present one or more names for each of the elective positions for the ensuing ten years, namely, president, five vice-presidents; secretary, assistant secretary, treasurer, five trustees, chairmen for each of the ten departments, five additional members of the committee on admissions."

D. *Standards for Admission.*—In addition to these motions which affect the constitution and by-laws, the convention should express itself as to the general policies to which the revision committee should adhere. The following are of medical interest:

Motion 7.—That there be admitted to the *Pharmacopeia* only those drugs whose medicinal value and superiority are generally acknowledged, and which are in general use in the United States.

Motion 8.—That the number of official preparations of these drugs be reduced to the effective minimum.

Motion 9.—That substances which are not used directly as medicines be not admitted to the body of the book; such as are needed only for manufacturing, testing, etc., being placed in an appendix.

Motion 10.—That no substance be barred solely because its assay is complicated.

Motion 11.—That physiologic assays shall be introduced whenever they are necessary and sufficiently accurate.

Motion 12.—That patents or trade-marks shall not exclude substances which are otherwise eligible; but that great conservatism shall be practised in the admission of proprietary substances.

E. *Secrecy.*—Secrecy should be eliminated.

Motion 13.—Secrecy is undesirable in official work. The revision committee should seek advice openly, and give opportunity for the public discussion of its findings before these are officially adopted. It should therefore devise a method of preliminary publication.

F. *Frequency of Revision and Issue of Supplements.*—The Pharmacopeia should aim to keep abreast with science. Since the additions to knowledge do not occur at stated periods, but are more or less continuous, the work of revision and, if possible, the publication should aim to be continuous:

Motion 14.—That the revision committee publish its conclusions as soon as possible after they are made, and that an interval of at least four months be allowed for public discussion before the conclusions are officially adopted; that once a year, or oftener if necessary, a supplement be issued, printed in such a manner as to be readily detached and inserted in the current pharmacopeia; that each supplement become official four months after the date of its publication; that a new issue of the pharmacopeia, embodying these supplements, be printed whenever and as often as the supplementary matter is of sufficient volume and importance to justify the board of trustees in printing a revised edition. That the greatest conservatism should prevail in regard to established standards of strength and processes.

G. *Dosage.*—The legal and moral responsibility for the treatment of a patient rests on the attending physician. Since he has this responsibility, he should have the right to prescribe whatever quantity of whatever substance he deems necessary for the treatment. This right must not be abridged in any manner. As a protection against errors of interpretation, however, the physician should indicate to the dispenser whenever he prescribes intentionally an unusually large dose of potent drugs. To make this protection possible, the maximum limit of the "usual" dose of such substances should be officially defined.

Motion 15.—That the revision committee is requested to introduce into the pharmacopeia a table of official "maximum doses" of potent drugs, in addition to the average doses; that it be stated, in a prominent place, that the insertion of these maximum doses is not intended to limit the right of the physician to prescribe larger doses; but as a protection to *him*, as well as to the public and the dispenser, against accidental errors.

H. *Working Method.*—As a method of obtaining the necessary data the following may be suggested:

Motion 16.—That the following outline be transmitted to the Executive Committee for their *consideration: The* consideration of any substance to be admitted to the Pharmacopeia shall originate with the committee on admissions, which shall communicate its decisions promptly to the chairman of the executive committee. The latter shall then assign the substance to the chairman of one of the departments (*3-9*), on whom the responsibility for securing a description shall rest. The chairman of this department shall then apportion the article among his associate members, and obtain what aid he may need from the other departments, and elsewhere, and render a report to his department for discussion. After alteration and adoption by this department he shall transmit his final report to the executive committee for vote. If adopted, the therapeutic committee shall affix the dose, and the editorial committee shall prepare the description for publication, submitting proof to the executive committee and to every member of the department in which the report originated.

Before concluding I should like to state once more that I offer these suggestions at this time for the purpose of evoking discussion. I do not flatter myself with the hope that they are perfect and infallible; but it is precisely by thoughtful discussion that their weak points may be made manifest. I shall be the first to welcome any and all improvements.

HYPERTROPHIC STENOSIS OF THE PYLORUS IN INFANTS

REPORT OF CASES OCCURRING ON THE PACIFIC COAST *

STANLEY STILLMAN, M.D.
SAN FRANCISCO

The uncertainty and conjecture surrounding every feature of this most interesting affection has induced me to contribute the following results of a study of all the known cases, occurring on the Pacific coast, of which I have been able to collect reports. This uncertainty involves not only the etiology, but the nosology, diagnosis, prognosis, treatment, and even the question of final cure. Only one thing seems positive, but that seems to be so everywhere, *that the more attention is* called to the affection, the more cases there are discovered, and all writers agree that the frequency of the affection is very much greater than the number of recorded cases would indicate.

The clear and complete description of the condition by Meltzer, of New York, at the meeting of the Association of American Physicians in 1898, and by Scudder and Quinby,[1] of Boston, leave nothing to be added in this particular by me. The symptom-complex of projectile vomiting, visible peristalsis, prominence of the epigastrium, and retraction of the lower half of the abdomen, scanty stools, and diminished secretion of urine, with or without a demonstrable tumor of the pylorus, suddenly appearing in the second or third week of life, is characteristic enough to awaken suspicion as to the nature of the affection. Koplik's recent paper has done much to harmonize the various theories and opinions regarding the nature of the disease, but I agree with Porter, of San Francisco, that so far as his classification is concerned, pure pyloric spasm should not be placed in such juxtaposition with pyloric stenosis. There is undoubtedly such a condition as pure pyloric spasm in infants, as in adults, without demonstrable hypertrophy of the muscles, either antemortem or postmortem, microscopically or macroscopically. Such a case was reported in our list—the patient was operated on for hypertrophic stenosis, but no tumor or stenosis of the pylorus was found. A gastroenterostomy was done nevertheless and the infant recovered from the operation, but died three weeks later from continuance of the vomiting. Spasm of the pylorus is far more apt to be secondary to trouble elsewhere in the gastrointestinal tract than the stomach, or a reflex from some other organ of the abdomen or pelvis, in adults and I believe also in infants, and is often a conservative effort on the part of Nature to prevent anything from passing into the intestine on account of some trouble below. A gastroenterostomy ought to and often does do harm under such circumstances, and possibly did do harm in the case of the infant mentioned. In infants I believe it will be found to occur later than hypertrophic stenosis, and to be the condition present in those cases of alleged hypertrophic stenosis, in which the symptoms begin after the first two months or so of life, and which make complete recoveries under medical treatment. The histories and symptoms of these cases ought to differ considerably from the others, and a careful study of them will, I am sure, enable a differential diagnosis to be made—the vomiting will not be so explosive or so constant, the peristaltic waves not so marked, the character of the stools different, the urine not so scanty, and the condition be more promptly relieved by medical treatment.

Our cases have thrown no new light on the etiology, but the fact has been amply demonstrated that the disease is characterized by the existence of a tumor of the pylorus, made up principally of hypertrophied muscles, both longitudinal and circular, but including as well all other structures constituting the pylorus, except the mucous membrane, as has been described by Prudden and others, and recently by Lee, of San Francisco. All pathologic examinations have shown practically the same conditions. It is incomprehensible that such a tumor, the size of an olive and as hard as cartilage, should be the result of any postnatal irritation arising in the first two or three weeks of life, when it is the fact that the condition occurs almost always in a previously absolutely healthy, strong, robust, breast-fed boy baby, and never occurs as the result of the numerous attacks of gastrointestinal disturbances in later infancy.

It is not within the scope of this paper to discuss any of the many theories for the cause of the hypertrophy, but I will dogmatically state that I believe the hard cartilaginous tumor will ultimately be found to be the result of a congenital abnormality of developmental origin, and not the result of swallowing amniotic fluid, or lanugo hairs or normal healthy mother's milk, and that its proper title will be admitted to be "congenital hypertrophic stenosis."

As certain as the fact of the existence of the hypertrophied muscle tumor is the fact of its capability of spasmodic contraction, and the degree of this spasm is not necessarily measured by the amount of hypertrophy present. In the two cases in which I operated, one patient being three and one four weeks of age, no suggestion of a lumen could be demonstrated by compressing the tumor, and there could be no doubt that the tumor was at the expense of the lumen. In the four postmortem specimens I have seen, one of them a fresh specimen, the same condition as has been repeatedly observed by others was found—a lumen reduced to a tortuous passage, one-half to three-quarters of an inch long, that would hardly admit a probe. In such cases the supervention or not of spasm is of no consequence —even when the muscle is entirely relaxed in death, the narrow lumen, filled with folds of reduplicated mucous membrane, is barely patulous. These are cases in which a tumor ought to be felt, and I think would more often be felt if repeatedly sought for, especially under an anesthetic. I think such examinations under an anesthetic are not frequently enough made, for it is of the highest importance, so far as prognosis and treatment are concerned, to determine the existence or not of a tumor. Tiny infants stand an anesthetic just exactly as well as adults, if not better, and show remarkably little after-effects. I strongly urge that such examinations be made in suspicious cases.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909.

[1] Scudder, Charles L., and Quinby, William C.: Stenosis of the Pylorus in Infancy, The Journal A. M. A., 1905, xliv, 1665.

Not all cases are of such an extreme type, however. In most the hypertrophy is not so great, the tumor so well defined, or the lumen so narrowed. These cases fall under Koplik's second division, are the ones that cause the greatest confusion, and are the ones of which I wish particularly to speak. They are the cases in which Loretta's operation has been done with more or less, generally less, benefit. They are the cases in which pyloroplasties of various kinds have been done; they embrace the postmortem cases in which the pylorus would admit a lead pencil; they are the cases in which after death the contracted lumen has been observed to increase in size to nearly normal, and in such cases the patients may entirely recover under medical treatment, or may improve but continue to suffer in some way or other all their lives. In these a tumor may be felt at some times and not at others, and might disappear when the spasm is relaxed in profound anesthesia. They are cases in which there is congenital hypertrophy of the pylorus, but not to a degree incompatible with the passage of food, except when spasm is added, and only moderate spasm may be sufficient to cause occlusion as complete as the organic occlusion in the class of cases first mentioned, which correspond to Koplik's third division. They differ from these only in the degree of hypertrophy, and this degree can be measured, so far as our present experience goes, only by the results of medical treatment or by exploratory incision. Such, in my opinion, are the patients that Robert Hutchinson, of London, cures by daily lavage of the stomach and the administration of minute quantities of very dilute milk, and by encouraging to reach a degree of exhaustion such that there is not vitality enough left in the muscles of the infant, pyloric or otherwise, to respond to any stimulus, and then the hypertrophied pylorus will relax enough to admit food to pass it. If it continues to do so permanently, as he says is the fact in his cases, I think it is because the degree of hypertrophy in his cases has been only moderate. It is partly due to his teaching, together with that of Pfaundler, Bloch, Heubner, and others, and partly to the poor showing made by surgery from including in its statistics cases of patients moribund at the time of operation, that makes the general practitioner uncertain what course to pursue when dealing with one of these cases, and makes him postpone surgical relief till it is as plain to the parents as it is to himself that the infant is about to die.

TABLE 1.—PATIENTS TREATED MEDICALLY

	Physician.	Location.	Date.	Onset.	Result.	Remarks.
1.	Barbat.	San Francisco.	../04	3rd Week.	Died (6 weeks).	Tumor found at autopsy.
2.	Baun.	" "	2/05	3rd Week.	Recovered.	Still requires soft food. No palpable tumor.
3.	Edwards.	Los Angeles.	../05	?	Died (8 weeks).	No autopsy.
4.	"	" "	?	?	Died.	Tumor at autopsy.
5.	"	" "	4/09	*8th Week.*	*Stationary.*	*Treated one month.*
6.	"	" "	5/09	?	Stationary.	Treated few days.
7.	Farmer.	Folsom, Cal.	11/08	Birth.	Died (16 weeks).	No autopsy.
8.	Frick.	Los Angeles.	12/08	3rd Week.	Stationary.	Weighs 7¾ lbs. at 6 mos. palpable tumor.
9.	Lewitt.	San Francisco.	10/08	3rd Week.	Recovered.	Weighed 13⅜ lbs. at 6 mos. palpable tumor.
10.	"	" "	11/08	3rd Week.	Improved.	Weighs 9¾ lbs. at 5 mos. palpable tumor.
11.	Porter.	" "	../09	4th Week.	Died (11 weeks).	Collapse; tumor found at autopsy.
12.	Spalding.	" "	../09	3rd Week.	Died.	Pneumonia found at autopsy.

TABLE 2.—PATIENTS TREATED SURGICALLY

	Surgeon.	Location.	Date.	Age.	Result.	Operation.
1.	Barbat.	San Francisco.	....	3 Weeks.	*Recovered.*	*Posterior gastrojejunostomy.*
2.	Eagleson.	Seattle, Wash.	?	?	Recovered.	Posterior gastrojejunostomy.
3.	"	" "	?	?	Recovered.	Posterior gastrojejunostomy.
4.	"	" "	?	?	Recovered.	Posterior gastrojejunostomy.
5.	Krone.	Oakland, Cal.	../07	12 Weeks.	Recovered.	Anterior gastrojejunostomy.
6.	Lartigau.	San Francisco.	9/08	3 Weeks.	Recovered.	Posterior gastrojejunostomy.
7.	Stillman.	" "	3/08	4 Weeks.	Recovered.	Posterior gastrojejunostomy.
8.	"	" "	6/08	3 Weeks.	Recovered.	Posterior. gastrojejunostomy.
9.	Tait.	" "	4/07	16 Weeks.	Died.	Gastroduodenostomy.
10.	Willits.	" "	3/08	9 Weeks.	Died.	Posterior gastrojejunostomy.

I do not think that it is as well appreciated by the average medical man, or perhaps by the average surgeon, as it ought to be, that infants, particularly in the first six weeks of their life, are as well able to stand surgical operations and anesthetics, and are as tenacious of life, so far as shock is concerned, as at any other time of their lives, provided certain precautions are observed, and these are that their vitality shall not have been lowered by starvation before operation, and that their body heat shall not be lowered by exposure during operation. Adults may sometimes be reduced in weight *before operation, with impunity, but not infants.* They begin to lose almost immediately in vitality and resistance, with loss of weight. Hence the urgency in this affection of early decision as to whether a given patient should be operated on or not.

The total number of cases I have to report is 27. The records were received in response to letters sent to representative physicians and surgeons throughout the states of Washington, Oregon, and California. The earliest case reported occurred in the practice of Dr. Barbat in 1904. In 1905, 2 cases were discovered; in 1906, 2 cases; in 1907, 1; in 1908, 13, and to date this year, 7 cases; in one case the year could not be ascertained.

Of these 27 cases, the diagnosis was verified by postmortem or operation in 15. Of the remaining 12, the diagnosis in 7 was made by men of the highest standing and experience; in one of these operation was urged but refused, and the infant died. In 2 others a tumor was present. The remaining 4 I class as doubtful.

Of these patients one died, and the records were lost in the fire of 1906. One has vomited since birth at intervals of four to ten days, and is now 5 years old. One is reported cured after three years, and one is now under treatment—a very recent case. Of the 27 patients 18 recovered and 9 died.

Eleven were operated on, of whom 9 recovered and 2 died. Sixteen were treated medically of whom 9 recovered and 7 died. Subtracting from these 27 cases the 4 doubtful ones, and a case in which no tumor was found at operation, there are left 22 undoubted cases of hypertrophic stenosis.

Of these patients 15 recovered and 7 died. Ten were operated on and 12 were treated medically. Of those operated on, 8 recovered and 2 died. Of those treated medically, 6 recovered and 6 died.

Of those recovering after operation, all have remained well and are healthy normal babies in appearance. Of those dying after operation, one died forty-eight hours after, and the other after a second operation performed five days after the primary one, which was a gastroduodenostomy and failed to relieve the vomiting. Of the six recovering under medical treatment, one at the age of 5 years is obliged to live on vegetable purées and milk and meat-juice. One has been under treatment one month and one ten days only. One at the age of 5 months weighs 7½ pounds; operation has been considered, but not advised because the mortality rate in the published statistics has been so discouraging. One at 6 months weighs 13½ pounds, and one at 7 months weighs 9¾ pounds. Of those dying under medical treatment, one died of double pneumonia, one of sudden collapse two days after beginning treatment. In two cases operation was urged but refused. The ten patients treated surgically were operated on by seven different surgeons, none of whom, I am sure, would lay claim to more than average skill or experience. The patients not operated on were treated by eight physicians, not counting consultants. Of the 6 living patients, 5 have been treated along the lines laid down in the past eighteen months; 1 was discharged cured five years ago, and still requires semisolid food. Of the 6 dying, 3 had the benefit of the best modern treatment, 2 were treated four and five years ago, and in 1 the character of the treatment is unknown.

As to the nature of the operations done, of the successful 8, 7 were posterior gastrojejunostomies and 1 anterior. Of the 2 fatal cases, 1 was a posterior gastrojejunostomy and 1 a gastroduodenostomy. If to the cases of gastrojejunostomies posterior and anterior we add the case in which no stenosis was found, but in which the patient recovered from the operation and died three weeks later from causes not chargeable to the operation itself, we have 10 cases of gastrojejunostomy with 1 death. The patient on whom a gastroduodenostomy was done, and a second operation five days afterward, would probably have recovered also had a gastrojejunostomy been done. If so, the record would have been 11 cases with 1 death.

These figures do not represent the results of the work of one or two brilliant and exceptionally experienced operators, but of seven different surgeons of average experience—and their significance lies in that fact. They do not represent triumphs of surgery, but of medicine—they are less the result of surgical technic than of intelligent and enlightened judgment on the part of medical practitioners. The babies still had a chance when operated on, and they lived and are all healthy, happy, robust babies to-day.

So far as the operation of choice is concerned, it seems to me to need no argument that it should be posterior gastrojejunostomy. While not ideal, perhaps, it succeeds and can be done more safely and quickly by the average surgeon than any pyloroplastic operation. Whether the pylorus in some cases recovers its patency, and the artificial opening closes or not, does not affect the main issue at all, to my mind. The babies so treated are, within a month, all normal well-nourished babies and have continued to be, while the medically treated ones have in some cases continued apparently cured for a long time, but in most have continued to suffer in some way for many months. One of the patients reported to us, but not included in our series because of lack of early history, has had periods of vomiting at average intervals of a week since birth six years ago; his present physician thinks that even yet he may advise operation. Of the six patients said to be cured so far as vomiting is concerned, one is still restricted to semisolid food at 5 years, a second weighs only 7½ pounds at 5 months; a third 9¾ pounds at 7 months; 2 are still under treatment, and only 1 is in positively satisfactory condition. This child weighs 13⅜ pounds at 6 months. Of the 6 patients dying under medical treatment, 1 died of pneumonia and 1 of collapse from heart trouble. Was not their starved condition responsible for their inability to contend with these affections, and are not all these infants, during the many weeks and months in which they are going down hill preparatory to "rounding the corner," as Hutchinson puts it, in greater danger of their lives from some intercurrent affection, or from failure to "round the corner," than they are from death due to a timely gastroenterostomy?

Our cases are, of course, too few to draw positive conclusions from, but those collected on this side the world have been too many; I have avoided combining them, because I did not wish to spoil our record. I think a new series should be started, combining all cases since Scudder's series of 1905—perhaps limited to cases occurring in this country, and if surgeons will refuse to operate in the last-resort cases the statistics will be such, I think, as to convince both practitioner and parents that there is less to fear from a timely operation than from timorous delay. While they do not justify positive conclusions, our cases afford food for reflection, and as the result of such reflection on my own part I may say that I believe that no one who has ever actually palpated one of the hard unyielding tumors found in the class of cases first mentioned can question the necessity of operation in them, and I think that the presence of a palpable tumor is a positive indication for immediate operation, whether the infant can apparently be benefited by medical treatment or not.

I think that cases of pure pyloric spasm can, and ought to be, in most cases, differentiated from all but the most mild cases of hypertrophic stenosis, and that they should probably never be treated surgically.

I think that medical treatment should be given while there is a reasonable doubt as to the diagnosis, in cases of hypertrophic stenosis plus spasm, in which no tumor can be demonstrated, but thereafter medical treatment should not be persisted in if the infant is losing ground; that control of vomiting in these cases does not mean cure, and that gastroenterostomy does not mean cure in at least nine out of ten cases, and that it is not so much a question of necessary operation as of unnecessary suffering, danger, and death.

2101 Webster Street.

Dosage for Children.—L. C. Ager, in *Pediatrics*, states that the dosage of drugs for children can not be calculated by any comparison of body weights. Almost all drugs are relatively better borne by children than by adults; this is probably due to more rapid elimination. On the other hand, there are some drugs that must be used with great caution with children. Probably the two extremes are atropin and arsenic. No drug in any dose should be administered without a definite idea as to the result that it will produce and then the amount used should be sufficient to produce that result. Almost as much harm has been done by thoughtless and injudicious use of vehicles as by the wrong use of active drugs. A teaspoonful of the various syrups frequently administered would upset the digestion of a healthy infant. Not infrequently also children receive an excessive amount of alcohol by the use of the elixirs or some of the proprietary foods.

PERFORATED GASTRIC AND DUODENAL ULCERS

WITH A REPORT OF TWENTY-TWO CASES *

JOHN H. GIBBON, M.D., and FRANCIS T. STEWART, M.D.
PHILADELPHIA

It has seemed to us that a study of twenty-two cases of perforated gastric and duodenal ulcers might be productive of some conclusions worthy of attention. This collection of cases represents our entire combined experience with this interesting lesion, all cases being included, whether successful or unsuccessful. Many of our patients were operated on in the same institutions, and in all but one instance the operation was done as soon as permission for it was granted and the necessary arrangements could be made. Neither of us has declined to operate in any case of this nature which has come to our notice.

Before taking up the discussion of the cases it will be well to consider the following brief histories of them. Cases 1, 2, 4 and 5 were reported[1] by one of us a number of years ago. These histories will be given only in brief.

The cases are presented chronologically.

Case 1.—F. C., male, aged 18; Bryn Mawr Hospital; perforated duodenal ulcer; closure and drainage; Jan. 13, 1903; sixteen hours after onset; recovery. (Gibbon.)

Comment.—The interesting points in this case are the following: There was nothing in the patient's previous history which could possibly indicate a duodenal ulcer; the attacks of pain which have been spoken of were supposed to have been due to the appendix. The patient had never had attacks of vomiting, nor had he ever passed blood by the bowel.

Case 2.—T. B., male, aged 50; West Chester Hospital; perforated gastric ulcer; closure and drainage, April 7, 1903, thirty-six hours after onset; operation advised by physician eighteen hours after perforation but patient would not consent; death eleven hours after operation. (Gibbon.)

Comments.—This case is a very typical one of acute gastric perforation presenting a typical history and the characteristic symptoms. If operation had been performed when it was first advised it is altogether possible that the patient's life might have been saved.

Case 3.—J. C., male, aged 24, operated on at Jefferson Hospital for perforated gastric ulcer, April 23, 1903, five hours after the initial pain; recovery. (Stewart.)

History.—The patient had never had indigestion and was enjoying good health up to 3 p. m. of the day of admission, at which time, after eating several lamb chops and a quantity of peas, he was suddenly stricken with violent pain in the region of the umbilicus, the pain later shifting to the neighborhood of the pylorus and then becoming generalized. The entire abdomen was tender and its muscles rigid, but both these signs were most marked in the right upper quadrant. The abdomen was scaphoid, liver dulness preserved, and no dulness could be detected in the flanks. The temperature was 97, the pulse 110, the respirations thoracic, the leucocytes 19,000, and the blood pressure 235. The patient had vomited his lunch, but there was no blood in the ejected material.

Operation.—A diagnosis of perforated gastric ulcer was made and the abdomen opened through the upper half of the right rectus muscle. There was a large quantity of odorless milky fluid in the peritoneal cavity but no gas. On the anterior wall of the stomach, about one-half inch from the pylorus and nearer the greater curvature, there was an opening about one-eighth of an inch in diameter, through which milky fluid and gas bubbled when the pylorus was handled. The surrounding stomach wall was markedly indurated. The opening was closed with a double row of continuous Lembert sutures of silk, some of which tore out, owing to the friability of the stomach wall. The peritoneum was normal in appearance. A second incision was made above the pubes, the entire abdominal cavity irrigated with salt solution, a gauze drain passed into the pelvis and another just below the pylorus.

Postoperative History.—The patient was placed in the right lateral posture and fed by rectum for one week. Recovery was uneventful.

Case 4.—M. S., female, aged 17; Bryn Mawr Hospital; perforated gastric ulcer; closure and drainage; May 1, 1903, forty-eight hours after onset; death twenty-four days after operation. (Gibbons.)

Comment.—This case was one of subacute perforation with the discharge of the gastric contents into the pelvis, and but for the complication which arose two weeks after the operation the patient would have recovered. This complication was the result solely of our failure to reintroduce the pelvic packing sufficiently deep to keep up drainage. This error is one which I (Gibbon) believe frequently results in death. It is often difficult to reintroduce the packing as deep as it ought to go, and we are too frequently content to get it simply within the peritoneal cavity. I would have lost a patient with gangrenous Meckel's diverticulum from the same cause had I not performed a second operation earlier than I did in this case and re-established drainage of the pelvis.

Case 5.—I. R., male, aged 45; Pennsylvania Hospital; perforated gastric ulcer; closure and drainage; Oct. 1, 1903, nine hours after onset; gastroenterostomy eighteen months later for recurrence of symptoms; recovery. (Gibbon.)

Case 6.—J. B., male, aged 32; operated on at the Jefferson Hospital for perforated gastric ulcer, Dec. 20, 1903, four hours after the perforation; recovery. (Stewart.)

History.—This patient had suffered for about five years with severe indigestion. While walking along the street he suddenly felt "ten thousand needle-like pains" shoot through his abdomen to the back, the right shoulder and the rectum. The pain abated somewhat and he ate a meal consisting of chops and potatoes, *immediately* after which the pain became excessive, being most marked in the epigastrium and later in the right iliac fossa. He took an emetic and vomited a large amount of semidigested food. There was marked rigidity and tenderness over the whole abdomen, absence of liver dulness and dulness in the flanks. The temperature was normal, the pulse 120.

Operation.—A diagnosis of perforated gastric ulcer was made and the perforation, one-eighth of an inch in diameter, found on the anterior wall of the stomach near the pylorus. The perforation was closed with a double row of continuous Lembert sutures of silk, the abdominal cavity flushed with salt solution, a drain of gauze passed to the vicinity of the pylorus and another through a separate incision into the pelvis. In this case the appendix also was removed.

Postoperative History.—Recovery was uneventful, except for a persisting sinus in the epigastrium, which healed after discharge of the silk suture with which the perforation had been closed. About five years after the operation the indigestion returned in a severe form and was treated medically with a happy result by the patient's physician, Dr. E. Q. Thornton

Case 7.—R. H. B., male, aged 44; Bryn Mawr Hospital; perforated gastric ulcer; closure and drainage, May 30, 1904, twenty-four hours after onset; death five days after operation. (Gibbon.)

History.—A diagnosis of gastric ulcer was made several years previous by Dr. Walter Chrystie. The patient had been sick a week with gastric symptoms including hematemesis. Twenty-four hours before operation he was seized with sudden severe abdominal pain. Dr. T. F. Branson saw him nine hours later and diagnosed perforated gastric ulcer. The abdomen was board-like but there was no obliteration of liver dulness. There had been no vomiting since the perforation occurred.

Operation.—There was a large amount of extravasation into the peritoneal cavity. The liver was adherent over the upper portion of the anterior wall, and from between the liver and stomach the gastric contents could be seen escaping. There was a large perforation near the lesser curvature, about the juncture of its first and second third. Ulcer closed by two rows of silk sutures. Suprapubic incision; thorough irrigation, with the escape of a large quantity of seropurulent fluid. Both wounds drained.

---

* Read in the Section on Surgery of the American Medical Association, at the Sixtieth Annual Session, held at Atlantic City, June, 1909. Owing to lack of space, the article is here abbreviated by condensation of the case reports. The complete article appears in the Transactions of the Section and the authors' reprints.

[1] Gibbon, J. H.: Am. Med., Dec. 19, 1903.

Postoperative History.—The patient did well until his second day, when he developed delirium tremens and died on the fifth day from this condition. His abdominal condition was perfectly satisfactory, but as there was no autopsy it was impossible to say what would have been the outcome but for the delirium tremens.

Case 8.—L. F., male, aged 27; operated on at the Jefferson Hospital for perforated duodenal ulcer, May 8, 1905, five hours after the perforation; recovery. (Stewart.)

History.—This man had had severe indigestion for one week. Immediately after drinking a large quantity of beer he experienced violent epigastric pain which radiated to the right shoulder and quickly spread over the entire abdomen. This was associated with great rigidity and tenderness; the liver dulness was undiminished, and no fluid could be demonstrated in the flanks. The temperature was normal and the pulse 90 and strong.

Operation.—A diagnosis of perforated gastric ulcer was made and the abdomen opened through the upper right rectus muscle. There was no extravasation of stomach contents, except a little mucus. The perforation was on the upper surface of the duodenum close to the pylorus and was about one-eighth of an inch in diameter. It was closed with silk, the abdominal cavity irrigated, and a small gauze drain placed in the wound.

Recovery was uneventful.

Case 9.—A. Z., male, aged 30; operated on at the Pennsylvania Hospital May 28, 1905, for perforated duodenal ulcer, twenty-four hours after the perforation; death within twenty-four hours. (Stewart.)

History.—The patient had been ill for twenty-four hours with severe abdominal pain and vomiting. There was general tenderness and rigidity over the abdomen, most marked, however, in the upper right quadrant; this with absence of liver dulness, led to a correct diagnosis. The temperature was 101, the pulse 140.

Operation.—An incision was made through the upper right rectus and a perforation found on the anterior wall of the duodenum near the pylorus. There were a number of adhesions and the peritoneal cavity was filled with pus and gastric contents. The perforation was closed with silk, the abdominal cavity irrigated and drained.

The patient died the following day.

Case 10.—W. W. H., male, aged 33; Pennsylvania Hospital; perforated gastric ulcer; closure and drainage, December 29, 1905, five hours after onset; recovery. (Gibbon.)

History.—The patient was seen with Dr. J. Norman Henry three hours after the sudden onset of severe abdominal pain, not relieved by 1/2 gr. of morphin. The abdomen was scaphoid and extremely rigid. The pain extended to the back and to the right shoulder. There was nothing in the previous history that threw any light on the case. The severe character of the pain and its radiation to the shoulder suggested gall-stone colic. The patient had never vomited blood or passed blood by the bowel.

Operation.—Immediate operation was done. Gas escaped as soon as the peritoneum was opened, making a diagnosis of perforation certain. The gas was followed by a large quantity of the gastric contents. The dissemination of this material was very general. A perforation was found on the anterior surface of the first portion of the duodenum; it was large and surrounded by considerable cicatricial tissue. Perforation closed with one row of catgut sutures reinforced with a portion of the lesser omentum. Suprapubic incision made and abdomen thoroughly irrigated. Both wounds drained.

Postoperative History.—The patient made a good recovery. He was fed by rectum until the eighteenth day, and is at the present time perfectly well.

Case 11.—E. F., female, aged 22, operated on at the Germantown Hospital, May 2, 1906, for perforated gastric ulcer, sixteen hours after the perforation. Recovery. (Stewart.)

History.—This patient had been treated for several years by Dr. R. P. Cummings for indigestion, associated with severe pain after eating and occasional attacks of vomiting. About sixteen hours before operation there was very severe pain in the abdomen, particularly in the right iliac region, but the greatest tenderness was in the left epigastrium. The abdominal muscles were rigid, the liver dulness normal, and no dulness in the flanks. The temperature was 99, the pulse 100, the leucocytes 24,000.

Operation.—A correct diagnosis was made and the stomach exposed through a median epigastric incision. A perforation ¼ inch in diameter and adherent to the anterior abdominal wall was found in the anterior wall of the stomach. There was no generalized peritonitis. The ulcer was closed with silk sutures and a posterior gastroenterostomy performed. The upper abdomen was irrigated and the abdominal wound closed without drainage.

The patient recovered and has remained well.

Case 12.—P. C., male, aged 29, operated on at the Pennsylvania Hospital, Oct. 27, 1906, for perforated gastric ulcer, twelve hours after the perforation; recovery. (Stewart.)

History.—This man had complained of indigestion for a number of months, a gnawing pain appearing in the region of the pylorus about two hours after eating and being relieved by eating. On the day of admission after breakfast the pain became excessive and radiated to the back and shoulders. This was associated with marked rigidity of the abdominal muscles. The liver dulness was normal and there was no dulness in the flanks.

Operation.—About twelve hours after the onset of the pain the abdomen was opened through the upper right rectus muscle and a perforation, 1/16 of an inch in diameter, found in the anterior wall of the stomach, near the lesser curvature and close to the pylorus. This was closed with silk sutures, and as only the peritoneum of the upper abdomen was soiled the foot of the bed was raised; a gauze drain was passed to the region of the perforation.

Recovery was uneventful, but about one year later there was recurrence of the indigestion.

Case 13.—McA., male, aged 45; Jefferson Hospital; perforated gastric ulcer; closure and drainage; Jan. 23, 1908; twenty-four hours after onset; death forty-eight hours after operation. (Gibbon.)

History.—The patient on admission to hospital was thought to be suffering from gall-stone colic and was treated for such. For ten days previous to admission he had suffered pain after eating. The family physician, Dr. Elinor Jones, reported that she had treated him several years previous for severe gastric symptoms. He was seen first eighteen hours after his admission when he had a board-like abdomen but no obliteration of liver dulness. His temperature was 97 and pulse very weak and about 104. The diagnosis of general peritonitis, due to perforated gastric ulcer, was made.

Operation.—The patient was in very bad condition with no pulse at the wrist. As soon as the peritoneum was opened gas escaped, followed by a profuse discharge of dark, thick fluid. The abdomen was so filled with this that two pitcherfuls of salt solution had to be used to wash it out before any structure could be recognized. The perforation, ¼ inch in diameter, was in the anterior wall of the pylorus; the ulcer being an old one. The perforation was closed with one row of linen thread sutures; a suprapubic incision was made; the cavity thoroughly irrigated; and both wounds drained. During the operation one quart of salt solution was injected intravenously.

Postoperative History.—The patient received the Murphy treatment for general peritonitis. He improved during the first twenty-four hours but grew worse the next day and died at 6 p. m.

Case 14.—B. S., female, aged 30, operated on at the Jefferson Hospital, April 9, 1908, for perforated gastric ulcer, three days after the perforation; death in thirty-six hours. (Stewart.)

History.—Mrs. S. developed excruciating epigastric pain three days before admission; this quickly became generalized and was followed by symptoms of peritonitis. There was continuous vomiting, marked distension of the abdomen, great pallor, and a pinched face. The temperature was 101 and the pulse 140 and thready. A mass was found in the right iliac region both on external and vaginal examination. This was afterward found to be due to adhesions among the intestines. A diagnosis of peritonitis, probably the result of a ruptured appendiceal abscess, was made.

Operation.—The appendix was removed and found to contain a segment of a tapeworm, but there was only slight inflammation of the mucous membrane. A second incision was made in the epigastric region and a hard mass about 2 inches in diameter and 2 inches from the pylorus found on the lesser curvature of the stomach; in the center of this indurated area was a minute perforation. The whole ulcer was inverted with silk sutures. There was a large quantity of purulent exudate throughout the abdominal cavity. After irrigation a gauze drain was placed in each wound.

Death occurred thirty-six hours later.

Case 15.—G. G., male, aged 42, operated on at the Polyclinic Hospital, July 14, 1908, for perforated duodenal ulcer, five hours after the onset of pain; recovery. (Stewart.)

History.—The patient had suffered with indigestion for several months. Just before supper he felt a severe knife-like pain in the epigastrium, shooting to the right shoulder and later to the right iliac fossa and throughout the abdomen. The tenderness was most marked in the epigastric region. The liver dulness was normal and there was no dulness in the flanks. The abdominal muscles were tensely contracted, the temperature normal, the pulse 110, leucocytes 15,000. There had been no vomiting.

Operation.—A diagnosis of perforated gastric ulcer was made and the abdomen opened through the upper right rectus muscle. There was a generalized serous peritonitis and a perforation about ⅛ of an inch in diameter in the anterior wall of the duodenum ¼ of an inch from the pylorus; this was inverted with silk sutures and a portion of the gastrohepatic omentum fixed over the suture line, owing to the friability of the duodenal wall. The peritoneal cavity was irrigated and the pyloric region drained with gauze.

Recovery was uneventful.

Case 16.—J. C., female, aged 60, was operated on at the Germantown Hospital, Aug. 11, 1908, for perforated gastric ulcer, four hours after the perforation; death in thirty-six hours. (Stewart.)

History.—Mrs. C. had had indigestion for a number of years and felt as if there was some obstruction at the pylorus. During the week before operation there had been epigastric pain and daily vomiting; blood was detected in the stools once. At 1 a. m. she was wakened from sleep with severe abdominal pain which was referred to the right iliac region. There was marked collapse, great rigidity of the abdominal muscles, and absence of liver dulness. The patient was seen with Dr. Edward Rhoads.

Operation.—A diagnosis of perforated gastric ulcer was made and the abdomen opened through the upper right rectus muscle. There was a large quantity of bloody fluid in the peritoneal cavity. The pylorus was hard, the induration extending 2 inches along the upper surface of the duodenum. There was a perforation just to the gastric side of the pylorus, about ¼ of an inch in diameter, with a piece of sloughing omentum plastered over it. The perforation was closed with silk sutures, and a posterior gastroenterostomy performed because of the narrowness of the pylorus and the previous obstructive symptoms. Owing to the extensive induration and the age of the patient a piece of the ulcer was excised for microscopic examination; no evidence of carcinoma was found by the pathologist. The abdominal cavity was flushed with salt solution and the right kidney pouch drained.

The patient vomited a large quantity of dark blood after operation and died at the end of thirty-six hours.

Case 17.—W. B., male, aged 20, was operated on at the Jefferson Hospital, Sept. 12, 1908, for perforated duodenal ulcer, twelve hours after the perforation; recovery. (Stewart.)

History.—The patient had never had indigestion or abdominal pain up until two weeks before operation, when he began to complain of pain about the umbilicus, more marked after eating. Twelve hours before operation the pain became intense and shifted to the right iliac region. At the time of examination there were evidences of a generalized peritonitis which seemed to be most intense in the region of the appendix. The liver dulness was normal and there was no dulness in the flanks. The temperature was 101, the pulse 100 and the leucocyte count 12,000. There had been no vomiting.

Operation.—A diagnosis of appendicitis was made and the appendix removed through a McBurney incision. It was normal except for the presence of several concretions. There was a large quantity of purulent fluid in the abdomen and adhesions could be felt about the pylorus. A second incision was therefore made in the epigastric region and a perforation ¼ of an inch in diameter found in the anterior wall of the duodenum near the pylorus. After peritoneal lavage a gauze drain was placed in each wound.

The patient made an uneventful recovery.

Case 18.—G. R., male, aged 48, was operated on at the Germantown Hospital, Oct. 12, 1908, for perforated duodenal ulcer, three days after the perforation; death in five hours. (Stewart.)

History.—There was no history of indigestion. The illness began with a sharp pain over the lower ribs on the right side, the pain being reflected to the back. The temperature was subnormal at this time; twenty-four hours later the patient developed a cough with mucous expectoration. The respirations were 40 and at the end of each there was acute pain in the mid-axillary line on a level with the fifth and sixth ribs, at which point a loud friction sound could be heard. The right chest expanded less than the left and there was dulness from the fourth interspace to the costal margin in the mid-axillary line, with impaired vocal fremitus and resonance. Numerous small râles could be heard over both lungs. The upper right rectus was moderately rigid but there was no tenderness in this area. The liver dulness was undiminished and no fluid could be detected in the flanks; the temperature was 100. We saw the patient at this time and thought the condition to be a beginning pneumonia. The following day there was marked improvement but on the third day the patient began to vomit quantities of dark fluid and passed a small quantity of bloody mucus by bowel. At this time we were asked to see the patient again. There was marked distention of the abdomen, absence of liver dulness, fluid in the flanks, no rigidity, and very little pain and tenderness over the abdomen. The leucocytes were 10,000, the pulse 90 and of poor quality, and the expression bad.

Operation.—It was thought that there was some intestinal obstruction or possibly a thrombosis of the mesenteric vessels, but owing to the seat of the initial symptoms the abdomen was opened through the upper portion of the right rectus. The liver was found pushed back by an enormous quantity of gas and foul black fluid. In the descending portion of the duodenum a perforation about ½ inch in diameter was found adherent to the under surface of the posterior and outer edge of the liver. It was exposed with great difficulty, sutured with silk, and covered with an omental graft. Irrigation was omitted and a large gauze drain passed down to the region of the perforation.

The patient died five hours later.

Case 19.—T. H., male, aged 43; Jefferson Hospital; perforated gastric ulcer; closure and drainage, Dec. 23, 1908, twenty-six hours after perforation; death fourth day after operation. (Gibbon.)

History.—The patient was seen with Dr. E. E. Graham. He gave a history of occasional attacks of indigestion but never vomited. Twenty-six hours before the operation he was seized with sudden severe abdominal pain. At the time of the operation much of the rigidity had disappeared, being displaced by a distention of the lower portion of the abdomen. He had all the evidences of an extensive peritonitis, and from its sudden onset was thought to be due to a perforation of the intestinal tract.

Operation.—Gas escaped as soon as the abdomen was opened. The pelvis was filled with thick pus. The appendix was removed and a second incision was made above the umbilicus. A perforation one-eighth of an inch in diameter was found near the lesser curvature, about one inch from the pylorus. Perforation was closed with a continuous gut suture, and both wounds drained.

Postoperative History.—The patient did remarkably well for three days but died on the fourth from a spreading peritonitis.

Case 20.—J. T. F., male, aged 50; Jefferson Hospital; perforated gastric ulcer; closure, posterior gastroenterostomy, drainage, March 7, 1909, seven hours after onset; recovery. (Gibbon.)

History.—The patient had had stomach trouble for twenty years. History was typical of gastric ulcer. The patient was seen first two hours after the sudden onset of severe pain, unrelieved by ¼ gr. of morphin given by his family physician, Dr. Himmelwright. Patient was anemic; his abdomen was scaphoid and of board-like rigidity; liver dulness was absent. The diagnosis of perforated gastric ulcer was easy.

Operation.—As soon as the peritoneum was opened there was an escape of gas. The perforation, measuring 1 inch in diameter, was found in the anterior wall of the pylorus. The ulcer extended all the way around the pylorus, and when the perforation was closed with a suture of gut and one of linen thread, the pylorus was completely obstructed. In the belief that there was probably a perforation on the posterior wall the lesser peritoneum was opened but no perforation was found. Because of the obstruction of the pylorus a posterior gastroenterostomy was done. When anastomosis was complete thirty-five minutes had been occupied in operation. A suprapubic incision was made, the cavity irrigated, and both wounds drained.

Postoperative History.—The patient was placed in the sitting posture and given the Murphy treatment. He made a prompt recovery and has remained well until the present time.

Case 21.—J. G., male, aged 53, was operated on at the Pennsylvania Hospital, April 10, 1909, for perforated gastric ulcer, seventeen hours after the perforation; recovery. (Stewart.)

History.—This patient had slight indigestion for several weeks previous to admission. Seventeen hours before operation and just before supper he was seized with a severe pain about the umbilicus which quickly became generalized. The temperature was 100 and the pulse 130; vomiting did not occur. The abdominal muscles were moderately rigid, although a large dose of morphin had been given. The tenderness was most marked in the right iliac region, leading to a diagnosis of appendicitis.

Operation.—The appendix was found to be normal and the peritoneal cavity filled with a purulent fluid. Adhesions could be felt in the right hypochondrium and a second incision was made in the epigastrium. This liberated a large quantity of air and pus and revealed a perforation one-eight of an inch in diameter in the anterior wall of the stomach near the pylorus. This was closed with silk, the peritoneal cavity irrigated with salt solution, and both wounds drained with gauze.

Recovery was uneventful.

Case 22.—W. P., male, aged 36; Jefferson Hospital; perforated gastric ulcer; closure, posterior gastroenterostomy; May 4, 1909, some days after onset; death twenty days after operation. (Gibbon.)

History.—The patient was admitted to the hospital suffering from an extensive peritonitis; very weak, with rapid pulse, and subnormal temperature. The abdomen was scaphoid and rigid, and liver dulness partially obliterated. The patient had been in bed three weeks suffering from nausea and vomiting. He was operated on one hour after admission. The time of perforation is indefinite but the patient had been suffering a great deal of pain for several days. His history indicated gastric ulcer.

Operation.—Gas escaped as soon as the peritoneum was opened and there was an extensive extravasation of the gastric contents. Perforation three-eighths of an inch in diameter was found in the pylorus; its edges were everted and hard; its closure, with one row of catgut sutures, nearly completely closed the pylorus and therefore a posterior gastroenterostomy was done. A suprapubic incision was made, cavity irrigated, and both wounds drained.

Postoperative History.—The patient was given the Murphy treatment and did well for two weeks, he then began to develop symptoms of septic infection and died on the twentieth day.

Autopsy.—The left chest was filled with pus and the lung was necrotic. There were a number of small collections of pus in the abdomen and a suppurating focus in each kidney.

PATHOLOGY

In these 22 cases the perforation occurred in the anterior wall of the stomach near the pylorus in 15 and in the anterior wall of the first portion of the duodenum in 7. The size of the perforation varied from 1/16 to ½ inch in diameter. It is our be[illegible] [illegible]l perforations are minute in the [illegible] they rapidly enlarge. Induration, indicating chronicity of the ulcer, was present in all of our cases. In three cases (4, 16 and 22), in which there had probably been a slow leak and then a sudden and profuse outpouring of the gastric contents, the perforation was large and the edges were thick and everted.

The extravasation has varied very much both in character and extent and depends largely on the acuteness and duration of the perforation. In the operations done in the early stages the extravasation consisted of the gastric contents. In the later stages it was found mixed with serum and pus. In only one case was the extravasation bloody. Plastic lymph was usually present about the site of the perforation, and in the delayed cases was often found about the ascending colon, cecum and small intestine occupying the pelvis. In one or two cases the appendix was covered with lymph, and but for a careful search would have caused the operator to think that here was the primary cause of the peritonitis.

In the large majority of the cases gas was free in the abdominal cavity and escaped the moment the peritoneum was opened.

SYMPTOMS AND DIAGNOSIS

In most of the cases a correct diagnosis was made before operation, and in all the symptoms were sufficiently urgent to demand immediate operation. In one case (18), owing to the atypical symptoms presented, the condition was not recognized at once. The following are the diagnoses made in these cases before operation: perforated gastric or duodenal ulcer, 15; acute appendicitis, 4; diffuse perforative peritonitis, 2; pneumonia and obstruction of the bowels, 1. It will be observed that the condition is most frequently mistaken for acute appendicitis. The history of previous indigestion extending over a long period; attacks of pain in the epigastric region, with vomiting; melena and more or less constant pain after eating, will aid greatly in turning attention to the stomach. In the slow perforations and early in the acute ones the extravasated material passes down the right side of the abdomen over the omentum or to the outer side of the colon to the right iliac fossa, and here gives rise to pain, tenderness and rigidity. Acute tenderness and rigidity is always present over the site of the perforation, however. The most typical history of the attack is that of a sudden severe pain, but little influenced by sedatives and accompanied by a board-like and scaphoid abdomen. Later with the diffusion of the peritonitis the abdomen becomes distended. With such a history and these signs alone perforation should be suspected and after the elimination, as far as possible, of other conditions, immediate operation should be done. Severe pain, tenderness and rigidity were present in all of our twenty-two cases. The pain is usually epigastric in the early stages and is apt to radiate to the back and sometimes to the right shoulder-blade, making confusion with biliary colic possible (see Case 13). Often the pain and tenderness later become most marked in the right iliac fossa, as the peritoneum in this situation becomes involved in a beginning and intense inflammatory process. The rigidity early becomes general in the acute cases and is absolutely board-like. The scaphoid and rigid abdomen constitutes one of the most marked and valuable signs of perforation and continues until the peritonitis becomes so far advanced as to produce distention.

The mistake is often made of expecting distention of the abdomen at the onset when there is a perforation of the stomach as the result of the escape of gas. Distention is never present in the early stages, and when present it indicates an extent and degree of peritonitis from which patients will seldom recover.

The absence of liver dulness associated with a scaphoid and rigid abdomen is an invaluable sign of perforation. When the abdomen is distended the diminution or absence of liver dulness is of little value. The preservation of normal liver dulness is no indication that perforation is not present. The liver dulness was diminished or absent in 6 of our cases; was normal in 9, and not recorded in 7. Movable dulness in both flanks was present in 3 cases, was absent in 7 and not recorded in 12. Vomiting after perforation had occurred took place in 12 cases; did not occur in 6 and was not recorded in 4. Vomiting of blood occurred in 2 instances.

Collapse is of variable occurrence and should not be expected. It takes place early and may be profound. It is by no means common, and its absence is of little significance.

Arrest of intestinal peristalsis, as determined by auscultation, occurs only after the peritonitis is sufficiently advanced to produce paralysis of the intestine. It may be a diagnostic aid, but is not a very reliable sign of perforation.

The temperature in the early stages is usually normal, subnormal or but slightly elevated. Even in the later stages it is a mistake to expect high temperature, although it may occasionally occur. The pulse-rate is usually increased, and the pulse may be very weak if collapse is present. The respiration is entirely thoracic and shallow and the respiratory rate is increased.

Leucocytosis was not marked in the early stages in this series of cases, although in some of the advanced cases it amounted to 24,000. We would say that little dependence can be put on the leucocyte count in making a diagnosis in the early stages of perforation. In practically every case the symptoms are sufficiently urgent to demand immediate operation, and no delay should be made for the study of the blood, although, when possible, this examination should be made without delay. The history of the patient may be of great value in determining the cause of the peritonitis. It is important to question him regarding stomach symptoms, especially the occurrence of pain coming on at a fixed period after eating or coming on at night after retiring. A history of vomiting and eructations of gas are significant. Often the patient will say that for years he has had indigestion or dyspepsia. In two of our cases a definite diagnosis of gastric ulcer had been made before perforation took place; six patients had been treated for "stomach trouble"; and in several others the symptoms were sufficiently significant to have indicated ulcer. A history of indigestion was present in 16 of our cases; was not present in 4 and could not be determined in 2. Melena sometimes occurs without other symptoms of ulcer and it should be inquired for carefully. A history of melena was given in 4 of our cases.

Age and sex are of no diagnostic value, but it is interesting to note in regard to sex that, although gastric ulcer has until recently been considered more frequent in women than in men, yet in these 22 cases of perforation there were 18 men and 4 women. As regards age our youngest patient was 17 years old and our oldest 60 years. Between 17 and 30 years, inclusive, there were 9 cases; between 31 and 40, 4 cases; between 41 and 50 years, 8 cases, and between 50 and 60 years, 2 cases.

The immediate cause of perforation may be very difficult to determine. In a few cases, however, it may be quite apparent. Any force either from within or without the organ which increases the tension of its walls may be the determining cause of perforation. In one of our cases the perforation occurred when the patient was lifting a buggy; another occurred after drinking largely of beer, and in several cases reported by others perforation has occurred after drinking a carbonated water.

TREATMENT

From our experience in these cases we are convinced that success or failure in the treatment of perforated gastric or duodenal ulcer depends almost entirely on the time which elapses between the perforation and its operative repair. Of the 13 patients operated on within seventeen hours, all but one recovered, while the remaining 9, all operated on after twenty-four hours, died. These figures are striking and significant and, moreover, are in fair accord with those presented by other operators. Occasionally, of course, one may be able to save a patient after one, two or even three days, but these will usually be cases of subacute perforation. The first point, therefore, in the treatment which we would emphasize is the importance of operating as soon as those early symptoms, already enumerated, of perforative peritonitis present themselves, whether or not we are able to make a definite diagnosis of their cause.

The abdomen should be opened through the right rectus above the umbilicus, an incision which gives the easiest and widest access to the viscera probably involved. If by chance an incision has been made below the umbilical line it is better to make another one above than to increase the first until the stomach and duodenum can be reached. The first incision should not be closed until the necessity for drainage of the pelvis has been determined by the extent and character of the exudate. If the symptoms have led the operator to make the lower incision and he finds the pelvis filled with exudate and an appendix or a Fallopian tube involved in the inflammatory process, but not in such a condition as to account for the extensive peritonitis, and especially if free gas is present, he should at once turn to the duodenum and stomach and assure himself that a perforation has not occurred. We know of one instance, at least, in which this mistake has been made and, therefore, warn against it.

The perforation having been found, it should be rendered as accessible as possible and closed. The method of closure must vary with the character of the ulcer and especially with the degree of induration about the perforation. In the simple cases with little induration a continuous suture may suffice, while in other cases the most carefully placed interrupted sutures may result only in an unsatisfactory closure because of the friability of the tissues through which they pass. These are the cases in which an omental graft will be useful. The sutures should be of the Lembert type and placed well beyond the edge of the perforation. A second row of sutures may seem to be indicated and should be used if they can be introduced without too much constriction of the caliber of the pylorus or duodenum. If the constriction is too great, then a portion of the lesser or greater omentum should be stitched over the first row of sutures. We have never employed excision of the ulcer and believe it to be unnecessary. The suture material employed in this series of cases has varied; one of us (Stewart) preferring to use silk and the other (Gibbon) chromicized or iodized catgut for the first row and linen thread for the second or linen thread alone if but one row is inserted. At this point the surgeon should assure himself that there is not a second perforation. In searching for the second perforation, however, one is not justified in opening the lesser peritoneal cavity for the purpose of examining the posterior wall of the stomach unless there is some distinct indication of a second perforation in this region.

The perforation having been satisfactorily closed, the next step in the operation is the toilet of the peritoneum. The question of irrigation at once arises and must be determined by the extent and character of the exudate. In all but one of our cases more or less irrigation was done. We believe that in the early cases with little extravasation simple cleansing with limited irrigation or moist sponges will suffice. When the extravasation is purulent or extensive, irrigation should be more or less general. It is a good plan to pour the irrigation fluid into the upper incision and allow it to flow into the pelvis and then out through a tube placed in the suprapubic wound. In this way the irrigation takes the course of the extravasated gastric contents. Evisceration is never indicated, and irrigation of every part of the abdominal cavity when the extravasation is limited to the right side and pelvis is a mistake. Drainage is necessary except in occasional cases of early perforation with little and limited extravasation. Drainage at the site of the perforation was employed in twenty-one of our cases and a pelvic drain also used in fifteen of these. In one of the successful cases no drainage was employed.

Gastroenterostomy may be indicated in addition to closure because the pylorus or duodenum has been shut off by closure of the perforation. We believe that this alone should be the indication for gastroenterostomy. In four of our cases a gastroenterostomy was done; in three because of the closure of the pylorus, and in the fourth with the idea of curing the ulcer. Two of the patients recovered and two died. In none of these could the result, either cure or death, be attributed to the gastroenterostomy. One of our main reasons for opposing gastroenterostomy in cases of perforation is that with proper after-treatment a cure can be obtained in nearly all of the cases. Even with considerable constriction of the caliber of the pylorus, liquids will pass and the tract will open up later, with the healing of the ulcer, to its normal capacity. There are distinct objections to performing a gastroenterostomy in the presence of a perforative peritonitis. In the first place, it prolongs the operation at least twenty minutes and it opens up to infection the clean lesser peritoneal cavity. Of course, there is some comfort after the patient has recovered in feeling that a gastroenterostomy has been done, but the justification for it in the majority of cases is very questionable. A subsequent gastroenterostomy may occasionally have to be done because of a recurrence of the symptoms. This was true in one of our twelve cases of recovery.

The after-treatment of these patients varies little from that in any case of peritonitis, excepting that rectal feeding is indicated in all cases in which closure without gastroenterostomy is done. It will be noticed that in our earlier cases we confined the feeding entirely to the rectum for a long period, but that in the more recent cases liquid nourishment was allowed by the mouth at a much earlier period without any marked difference in the results. Large quantities of salt solution by the rectum were used in the cases in which the peritonitis was extensive or of long standing.

The question of posture is one about which surgeons will probably always differ as we do. One of us (Stewart) believes that the right lateral posture is the one always to be preferred. The posture must be influenced to some extent by the situation of the drains. Where drainage at the site of the ulcer only is employed Stewart has used always the right lateral position and occasionally elevated the foot of the bed. Where a pelvic drain has been used Gibbon has always employed the Fowler position or some modification of it.

RESULTS

The results obtained in these cases may be divided into immediate and ultimate. In the twenty-two cases reported there have been ten deaths (all but one occurring in cases of operation more than twenty-four hours after the perforation) and twelve recoveries, all of patients operated on within seventeen hours after the perforation. In two of the fatal cases life was prolonged for three weeks. The table shows the time of operation and the results.

TABLE OF TIME OF OPERATION AND RESULTS

Case.	Time Between Perforation and Operation.	Cured.	Died.	Time of Death After Operation.
1.	16 hours.	1		
2.	36 hours.		1	11 hours.
3.	5 hours.	1		
4.	48 hours.		1	24 days.
5.	9 hours.	1		
6.	4 hours.	1		
7.	24 hours.		1	5 days.
8.	5 hours.	1		
9.	24 hours.		1	24 hours.
10.	5 hours.	1		
11.	16 hours.	1		
12.	12 hours.	1		
13.	24 hours.		1	48 hours.
14.	3 days.		1	36 hours.
15.	5 hours.	1		
16.	4 hours.		1	36 hours.
17.	12 hours.	1		
18.	3 days.		5	5 hours.
19.	26 hours.		1	4 days.
20.	7 hours.	1		
21.	17 hours.	1		
22.	Some days.		1	20 days.
		12	10	

The causes of death open up an interesting subject. Six of our ten deaths occurred within about forty-eight hours, presumably as a result of the peritonitis; one patient died twenty days after operation from general sepsis, pus being found postmortem in the pleura, abdomen and both kidneys; another died on the fourth day from an extension of the peritonitis; another on the twenty-fourth day after the perforation and seven days after a second operation done for obstruction, the result of a pelvic abscess; still another died on the fifth day from delirium tremens, the abdominal condition being satisfactory.

Except in one case in which a gastroenterostomy was subsequently required, all but one of the twelve patients who recovered have remained well. This one patient developed gastric symptoms some time after his operation, but these disappeared under medical treatment.

1608 Spruce Street—311 South Twelfth Street.

ABSTRACT OF DISCUSSION

ON PAPERS BY DRS. STILLMAN AND GIBBON AND STEWART

Dr. W. J. Mayo, Rochester, Minn.: When I began the practice of medicine and surgery, operation for hernia was not considered until there was strangulation. We came to the point later when we no longer waited for strangulation, but operated on certain patients who had been strangulated. Later, it seemed advisable to operate before strangulation could again occur. Later still, we came to the step of operating on patients to whom wearing a truss was disagreeable or in whom it was effectual, and now we operate without question as to whether there is any likelihood of strangulation occurring or not.

Almost the same conditions have been experienced in regard to appendicitis. We no longer wait for an abscess to form or for peritonitis to occur, but operate early. Dr. Deaver's and Dr. Ochsner's papers show clearly that pancreatitis is usually the result and a late result of gall-stone disease. We should not wait for these conditions to appear. And, finally, the last two papers show that the mortality of these operations is not from the operation *per se*, but rather from the condition, and this depends largely on the length of time patients waited before operation was considered.

I endorse what Dr. Stillman said in regard to the second group of cases apparently of hypertrophic stenosis, in which the patients recover. I am no longer certain that they do recover. We have a small group of patients who give typical signs of moderate stenosis when infants, but recover or partially recover, and then drag along for many years, finally come to operation which discloses a condition of partial hypertrophic stenosis which had caused much suffering and disability. The removed specimens show clearly the same pathologic conditions which existed in the infants operated on for stenosis.

In the treatment of the hypertrophic variety, I agree with Dr. Stillman that the posterior gastroenterostomy is the better operation of the two. To one who has actually had these almond-shaped tumors in hand at the operating table, it certainly looks as though a plastic operation would not be so safe as gastroenterostomy.

Drs. Gibbon and Stewart said that nearly all their patients had previous symptoms of ulcer, lasting for years before operation took place, and that those operated on within seventeen hours after perforation occurred, nearly all recovered. Those operated on later did not. I think that we should consider in the question of perforation that there are two classes of ulcers, the acute and the chronic. Where is the ulcer that Watson describes so beautifully and of which Fothergill wrote? The girl who while hanging up clothes on a line falls in a heap and the postmortem shows not one but many perforations! That is a rare form of disease and it is an acute toxic ulcer. I have seen but one such case in my experience. The ulcers we do see have not been described, because the patients do not die suddenly, but from a general peritonitis, and the real origin of the trouble has been obscured by secondary conditions and complications. We must always bear in mind that the postmortem does not show the condition as it existed in life, but that of which the patients died.

Speaking finally of the operation itself, I wish to endorse what Dr. Gibbon has said in regard to the operative treatment. It is better to close the ulcer and to drain, and then, if necessary, do a gastroenterostomy later than to do a primary gastroenterostomy, because, in the experience of von Eiselsberg, as well as of ourselves, the perforating ulcer cures itself. We have not had a single case of perforation in which there was relapse of the ulcer, and when trouble did appear late it was a secondary stenosis and not a return of the disease.

Dr. Joseph C. Bloodgood, Baltimore: I wish to emphasize what may be called suprapubic exploration and pelvic drainage. Dr. Gibbon and his associates in the Pennsylvania Hospital, Philadelphia, have demonstrated the importance of pelvic drainage in all cases of general peritonitis. In all doubtful abdominal cases my experience teaches me that the suprapubic incision will allow better than any other single incision the best view of a rapid diagnosis. For example: In pancreatitis, especially acute cases, the suprapubic incision will expose the omentum and its fat necrosis at once and clinch the diagnosis. In one of my cases this was of great help, because when I made the incision to expose the pancreas I found no positive evidence of the disease until the pancreas was exposed through a great mass of fat. Another advantage of the suprapubic incision in all cases of peritonitis is that through this incision you can at once remove with gauze wet in salt solution the exudate; then you can pack the pelvis and other parts of the abdomen with gauze wet in salt solution. Now, while the surgeon is attacking the focus of the infection, whatever it may be, the patient is getting the advantage of this extensive drainage, which might be called temporary drainage. I have had a number of cases recently in which I have employed this temporary pelvic drainage, while I was attacking the focus of infection—appendix or stomach perforation—through a second incision.

In regard to perforation of the stomach, not the non-traumatic perforation, but those following bullet wounds, I would urge exploration of the posterior wall of the stomach in every case. In a recent case in which the patient recovered, I found for the first time that the best way to explore the posterior wall of the stomach is to approach the stomach as when performing a posterior gastroenterostomy. That gives a better view than can be obtained in any other way. Besides, this is close to the pancreas and we can drain through the opening in the omentum between the stomach and transverse colon. This drainage of the pancreas is an important point in treatment of perforation of the posterior wall of the stomach.

Dr. F. C. Shattuck, Boston: We physicians, pure physicians, owe a great deal to surgeons and to their work of the past few years. For instance, our knowledge of peptic ulcers was formerly necessarily limited to the clinical symptoms and postmortem findings; we rarely felt justified in making the diagnosis in the absence of hemorrhage. As regards the postmortem findings, as Dr. Mayo well said, a distinction must be drawn between the disease and the results of the disease. Surgeons are, in a sense, vivisectors. They see disease and its results in the living body and have transferred many conditions from the incurable to the curable class.

As a physician, I am, naturally, conservative as regards operation, and I think that some surgeons have been too ready to operate for digestive disturbances. I see patients who have been operated on for gastric symptoms who are in no way the better for the operation. They have recovered from the operation, but they have not recovered from the disease nor have they been relieved of their symptoms. This remark has a wider application than simply to gastric cases. A busy practitioner in the vicinity of Boston, a first-class man in every way, said to me recently: "It is all very well, this modern surgery. The surgeons operate on patients, discharge them as cured, and then we have to take care of them for years." The fact that a patient can recover from an operation is not, of course, sufficient reason for doing an operation. It may be more blessed to operate than to be operated on. With any new procedure the pendulum is apt to swing too far at first, but it will swing back, an equilibrium will be found, knowledge will be increased, humanity will be benefited. In all this surgeons are playing an important part in which we physicians want to be helped and to help even by criticism.

Dr. William W. Skinner, Geneva, N. Y.: Regarding the perforation of the stomach by bullets, we should not forget that the enlarged anterior bullet wound may furnish a convenient avenue for exploration and suture of the posterior stomach wall. In several instances I have done this successfully. Regarding the so-called medical cures in cases following gastric ulcer, I have recently had two cases in which stenosis following gastric ulcer had produced an enormous dilatation of the stomach. These patients had been treated by electricity, by diet and various other means, and since two weeks after the operation, after a period of from five to twenty years of suffering from dyspepsia and vomiting, and in recent months an inability to take any solid food, these patients are now eating everything without any distress whatever. These patients had run the entire gamut of nerve specialists, stomach specialists, and what-not. I wish simply to add these cases to those already mentioned.

Nervous Prostration.—A close analysis shows that the real cause of most so-called nervous prostration is failure of adjustment to environment, and is psychogenetic.—T. A. Williams, in the *Kansas City Medical Index-Lancet.*

PELLAGRA, ANCIENT AND MODERN

HOWARD D. KING, M.D.
NEW ORLEANS

Though the fact may not be generally known, it is none the less true that pellagra, cases of which are frequently coming to notice in various sections of the United States, has existed among us for many years unrecognized or, probably, erroneously diagnosed, and attracted but little attention. The startling developments of the disease in its various phases in this country during the past two years have aroused such keen interest, and in some cases anxiety, in the subject of the "new" disease, from both professional and lay points of view, that it may not be a waste of serious effort to inquire into the geographical distribution of the disease. Before referring to the history and published reports as to the occurrence and incidence of the disease, it will be worth while to study briefly the early history of maize, *Zea maidis*, which undergoes deterioration and, thereby, causes the disease under discussion.

Maize, otherwise known as Indian corn, *Zea maidis*, is of the natural order *Graminaceæ*. Stephen Ladislaus Endlicher, a noted Hungarian botanist and professor of botany at the Vienna University (1840) and author of "Genera plantarum," states that, while little of it is known in its natural state, it is probably indigenous to tropical America. Bonafon, a French naturalist and the author of "Histoire naturelle du Maïs," asserts that corn had been cultivated from a very ancient period in the Asiatic islands under the equator, and quotes three authorities (Bock, 1532, Ruel and Fuchs) in support of this statement.

From Asia, corn was soon introduced into China, and shortly after the beginning of its cultivation there was transported westward. Later it was observed in India and Turkey, in the latter country being termed "Turkey corn," under which designation in the year 1597 John Gerard, an English surgeon and botanist, described seven varieties, and one species particularly which he called "Corne of Asia."

Both Gerard and Bonafon maintain that maize was first found in the far East, and that following the discovery of America it was reintroduced into Europe from that country. Embodied in Bonafon's work is a drawing of corn reproduced from a Chinese treatise on natural history, "Li-chi-tchin," dated 1562, seventy years after the discovery of the New World by Columbus. Santa Rosa de Viterbo, a Spaniard, declares, in conflict with these writers, that maize was introduced into Spain by the Arabs in the thirteenth century. Egyptian writers and students of archeology assert that they have never seen the likeness of corn reproduced on Egyptian monuments. Travel throughout Asia and Africa was quite extensive during the twelfth to the fifteenth centuries, inclusive, and yet no mention of corn is made until the sixteenth century.

That the views of both Bonafon and Gerard were erroneous is evident from the fact that the expeditions to the New World undertaken by Ponce de Leon, Hernando Cortez, Francesco Pizarro, Lucas Vasquez de Ayllon and Pamphilo de Narvaez, all in the beginning of the sixteenth century, had as members of their parties many who had previously traveled in the far East and they knew nothing of corn and had never seen it before their arrival in America. During the disastrous excursion of Pamphilo de Narvaez into the interior of Florida he and his companions seized several hundred bushels of corn from the Indians at a bay which they called the "Baia de Caballos," now Apalachee Bay; this was the first experience of the Europeans with corn as a foodstuff.

Baron Friedrich Heinrich Alexander von Humboldt, a celebrated German scientist and author, published in 1814 to 1834 the results of his American journey in a large series of volumes bearing the general title, "Voyage aux régions équinoxiales du nouveau continent." In this work Humboldt furnishes conclusive proof that maize was first found in America; that its introduction into Europe was not a reintroduction, and that at the time of the discovery of the New World it had long been cultivated there, "green corn" being considered an important item of food by the Indians. Many of the tribes celebrated its season with religious ceremonies and festivals.

Evidence as to the correctness of Humboldt's statement is found in the fact that in 1600 Baruino, in a medical treatise, called attention to a peculiar malady prevailing among certain tribes of the American Indians. From his meager description it apparently resembled the pellagra which we have to-day; and he ascribed it to the use of corn, which formed a part of the Indian's daily diet. Francesco Scipione, Marchese di Maffei, an Italian poet, archeologist and litterateur, a few months after the appearance of Baruino's treatise, made similar observations. At this time various travelers returning from the New World called attention to a disease noted in horses, as a result of which the animal becomes paretic and tabetic and also loses hair. This affliction in the horse was thought to be caused by eating bad corn. All of this evidence obviously demonstrates that the North American continent is the natural habitat of *Zea maidis* and consequently the original home of pellagra. The first mention of the disease in literature was made by Ramazzini, who called it "mal del padrone."

The first really authentic accounts of the disease come from Spain, where corn was introduced during the period of 1680 to 1700. It would appear that in 1735 it was observed in the vicinity of Oviedo, and twenty-seven years later, or 1762, Gaspar Casal describes the disease which he has seen in the Asturias and gives to it the name "mal de rosa." The term "lepra scorbutica" and "asturiensis" is also said to have originated with Casal. Among the peasantry the disease was at different times termed "mal de la rosa," "mal del sole" and "mal de la miseria." When the disease was found in this region it remained for a long time confined within very narrow limits. Oviedo is still the principal focus of the disease, but it is also prevalent in Cuenca, Lower Aragon, Saragossa, Navarre, Burgos and other provinces.

In Italy the disease was first reported from the neighborhood of Lago Maggiore, and in 1750, fifteen years after its first noticed appearance in Spain, it broke out simultaneously in the districts of Milan, Brescia, Bergamo, and Lodi. From these points it spread rapidly to Como, Cremona, Mantua and Pavia, and before the year 1798 the whole of Lombardy was a very pellagrous region. At the time of the wholesale infection of the Lombard region, the disease became endemic in Venetia on the one side and in Piedmont on the other almost simultaneously. With the beginning of the year 1800 the course of the disease was southward, and soon Emilia and Tuscany were invaded, the disease, however, becoming more prevalent in its original and earlier seats. Frapolli, physician to the Hospital of Milan, clearly described the disease in 1771, nine years after Casal had described the disease as "mal de rosa." To

Frapolli we owe the present name of the disease (from *pelle*, skin, and *agra*, rough), and the same writer declared that the disease was an ancient one and none other than pellarella, having been noted in 1578, as would be seen by reference to the regulations for admission to the Hospital Major of Milan at that time. At about the time Frapolli named the disease, Adoardi of Venetia called it "scorbutus alpinus." The disease spread to such an extent that the Venetian authorities, at the request of the Sanitary Commission of Venice, issued an edict in 1776 prohibiting the sale or exchange in the public markets of corn having a bad odor or taste. As a proper designation of the disease (corresponding to the symptoms observed), D'Oleggio in 1784 suggested that it be termed vernal insolation—the "sunburn of spring." During the same year the Joseph II Pellagra Asylum, a hospital for the special study of the disease, was established in Legnano by royal warrant, and the older Strambio appointed as chief physician. Giambattista Marzari, about 1810, was the first to call attention to the probable relation between maize and pellagra; and sixteen years later (1826) Vincenzo Sette declared that the principal cause of pellagra was fungi, producing acid decomposition in the fatty oils of the corn.

With the exception of the proclamation of the Venetian authorities, very little was done to check the ravages of the disease until Ballardini, in 1845, declared and demonstrated that pellagra was caused by eating damaged maize. His views as to the causation of the disease met with contemptuous ridicule from many quarters. While the discussion as to its cause waxed warmer the disease raged to such an extent that in the space of seventeen years (1839 to 1856) it increased from 14 to 28 per thousand, or from 20,282 to 38,777. This alarming increase aroused the Lombard government to action, with the result that a special commission was appointed from the Instituto Lombardo to look into the cause of the malady. This commission differed in its opinion from Ballardini. The report stated that, though Ballardini's theory as to damaged maize being the causative factor in the production of the disease was correct, the commission could not concur in his opinion that a diet free from maize influenced the disease; their own conclusions being that such a diet did not affect the progress of the disease one way or the other. The final conclusions of the commission certainly are not in accord with their first findings as to Ballardini's theory. All improvements in the condition of the afflicted peasantry or decline in the disease they attributed to better conditions of alimentation, and it may easily be seen that their findings were affected, at least in a measure, by an element of personal prejudice.

In the province of Vicenza the number of persons known to be pellagrous between the years 1853 to 1855 was 1,380; in 1860, 2,974, and in 1879 it had risen to 3,400; these figures, it will be noted, covered only one province. In 1879 it was estimated that the number of pellagrous peasants numbered 97,855, the distribution being as follows: Lombardy, 40,838; Venetia, 29,386; Emilia, 18,728; Tuscany, 4,382; the Marches and Umbria, 2,155; Piedmont, 1,692; Liguria, 148; Rome, 76. In Lombardy, where the disease has always attained its maximum, the most infected centers have been in the provinces of Brescia, Pavia, Piacenza and Ferrara. Next to Lombardy the disease raged most severely in Venetia and Emilia. In Lombardy, Venetia and Emilia, the number of persons actually afflicted with the disease (1880) formed 31.70, 30.52 and 23.66 per thousand of the agricultural population. That pellagra seriously affected the military recruiting in this section of Italy may be seen from the army report of 1878, wherein it is stated that 20 per cent. of the conscripts in Lombardy and 18 per cent. in Venetia were unfit for military duty by reason of pellagra. In 1874 the total number of known pellagrous lunatics in Italy was 945. In 1877 the number had increased to 1,348. Between the years 1879 and 1881, a period of two years, the disease had increased from 97,855 to 104,067. In 1899 the number of pellagrous peasants showed a slight decline, there being only 72,603 cases, or 10.30 per 1,000, reported. It is interesting to note that Lombardy, always the greatest stronghold of the disease, was surpassed by Venetia in the total number of cases according to the statistics of 1899, the figures being: Venetia, 39,882, or 34.32 per thousand, and Lombardy, 19,557, or 12.90 per thousand.

In a government report, "Annali di Agricoltura, No. 18," published in Rome, 1880, under the caption, "La Pellagra in Italia" (1879), the statistics for the St. Clement's Hospital of Venice for the period of the preceding six years are given, and it is not too much to say that they are startling. From it one may obtain some conception of the extent of the disease which the Italians so graphically call "il delirio della miseria."

The figures are as follows:

	Total No. Insane.	Pellagrous Insane.
1874	558	178
1875	595	153
1876	666	175
1877	802	215
1878	859	294
1879	924	337
Totals	4404	1352

In 1884 it was conservatively estimated that there were 10,000 pellagrins in Italian hospitals and insane asylums. A bill for the better prevention of pellagra was introduced in the Chamber of Deputies at Rome through the efforts of the Zannardelli cabinet in the spring of 1902. In 1903 it was calculated that there were in Italy 60,000 cases of pellagra. According to Dr. L. W. Sanbon, however, these statistics are very unreliable for the reasons (1) that the disease is one that is not usually admitted by the victim because it is by many considered degrading; (2) that the notification of its presence to the authorities is not compulsory; and (3) that the local authorities very often, for obvious reasons, endeavor to make it appear that it is decreasing in their respective districts. Sanbon believes that it would be no exaggeration to place at the figure 100,000 the cases in which the disease is plainly manifest; of these, 3,000 at least are in the lunatic asylums of the kingdom. The statistics of 1907 show no appreciable decline of the disease, and conditions, instead of being bettered, are stationary, though there has been a marked decrease in the number of deaths, from 3,987 in 1898 to 376 in 1907.

From France we obtain the following data: The first reliable information of the existence of pellagra in Gascony came from the vicinity of Arcachon in the year 1818, after which it spread along the coast of the Gironde and the Landes. Marchand, in 1826, called attention to the disease in the southern provinces of France. Dr. Petit, a French physician, took note of it about 1828, and states that it was more common in the Landes than in the Gironde district and that at one period in his memory there were 200 cases out of a population of 6,000. Lavinder states that the disease was first observed in France by the elder Hameau in the vicinity of Teste in the early part of the nineteenth century, 1818 (whence the name, "maladie de la Teste").

After leaving the Gironde and Landes districts the malady spread along the left bank of the Garonne and toward the Pyrenees mountains. In the vicinity of Dax the disease never assumed serious proportions.

At intervals, even at the present day, our attention is called to cases occurring in various parts of France.

Tuczek, in 1893, stated that 2 per cent. of the Spanish peasantry were pellagrous.

In Roumania the first recorded case was in 1810, and the medical profession is unanimous in tracing the disease to damaged corn imported from Italy by vessels in the coast trade. From the period between 1833 to 1846 the disease attracted much attention and was known to the people under the name of of "Buba Tranjilar." Between 1854 and 1859 it had increased considerably and gave much alarm to the government, as at that time the records pointed to 4,500 known cases, Moldavia having more cases than Wallachia. In 1885 there were 10,626 cases; in 1886, 19,797 cases. In 1898 the peasant population of Roumania was estimated at 5,300,000. Of this number, according to statistics, 21,272 were pellagrins. Triller, in 1906, calculated the number of pellagrous peasants in this country to be not less than 30,000, and possibly many more. In 1907 the number of pellagrins were supposed to number not less than 40,000. Conditions in Roumania, the same as in Italy, instead of improving, seem to have become aggravated.

Corfu, an island off the coast of Epirus, has also had its share of pellagra, the disease becoming endemic in that island beginning with the year 1856. In Corfu it exists in more than 30 out of a total of 117 communes, the proportion of cases for the whole island being 3.2 per 1,000 inhabitants. Typaldos, of Corfu, has given the disease a great deal of study.

The disease exists in Austria, where the Tyrol region has been the area most affected. In Bukowina, having a population of 38,000, pellagra affects 2.9 per cent. of the peasantry, and there are seventeen institutions in Austria for supplying the peasants with proper food. Austria has enacted legislation dealing with pellagra and, aided by popular education, the government expects to keep the disease within bounds.[1]

In Great Britain, peculiarly enough, the disease has been noted but twice, the first case being reported by Drs. Brown and Carruthers,[2] of Rock Ferry, England. The second case was reported by Drs. R. Dods Brown and R. Cranston Low,[3] assistant physicians in the Royal Edinburgh Asylum, in which institution it occurred in the current year.

In Africa pellagra was first recognized in 1847 by Pruner, who had studied the disease in Italy. Pruner's statements were criticized by Hirsch and others. Years later at a meeting of the medical congress held at Cairo from Dec. 18 to 23, 1892, Dr. F. N. Sandwith, M.R.C.P., and senior physician and lecturer on medicine at Kasr-el-Aini Hospital, Cairo, made a report on the disease and read a very able paper on its prevention. He states that, through the courtesy of Dr. J. Wornock, superintendent of the lunatic asylum of that region, he was able to note annually forty to fifty cases of pellagrous lunatics. Sandwith has seen more than 1,100 cases since 1893, and states that the disease is frequent in Lower Egypt, though not so prevalent in Upper Egypt. He declares that the percentage of pellagrins who become insane in Egypt is far lower than that of Italy. In June, 1902, Sandwith journeyed through eleven villages of Gharbieh and examined 315 men. Of these, 114, or 36 per cent., showed signs of early pellagra. An American, Passed Assistant Surgeon C. H. Lavinder, of the U. S. Public Health and Marine-Hospital Service, one of the foremost students of the disease, differs from the above statement of Sandwith, stating that the disease occurs rather extensively in Upper Egypt. The disease is endemic between 42 and 46 degrees north latitude, 11 degrees west and 26 degrees east longitude of Paris. The island of Corfu and several other small foci are outside of this area.

The disease has been observed in Algeria, Tunis, Bulgaria, Servia and in various sections of southern Europe. Reports as to the recognition of the disease have also been received from northern Portugal, Dalmatia, Croatia, Bosnia, Turkey, Bessarabia, Kherson and as far north as Poland. Low, one of the later investigators, while in Italy in company with Sanbon, saw several cases, and reported that it was the same disease he had encountered in the West Indies. Neirte has reported the disease from New Caledonia. Ray, in 1902, stated that he had noted several cases of pellagra in one of the districts of North Behar, India.

In the Americas, pellagra has been recognized in Barbadoes, Brazil, Uruguay, the Argentine Republic, and in Mexico in more recent years by Bouchard, as well as in the United States.

In the United States, sporadic cases of pellagra were recognized in New York and Massachusetts hospitals as early as 1863 and 1864. It was about this time that reports were received of an epidemic from the vicinity of Halifax, Nova Scotia. Reports of this outbreak of the disease were very meager and uncertain. It is a matter of interest that the medical records and memoirs of the Civil War do not contain any specific instances of cases bearing a resemblance to pellagra having occurred during the long struggle. Certainly, the culinary methods of the troops in the field at that time were anything but good.

In this connection it is fair to assume that every one recalls that during the war there were several large prisons or camps in the South created for the detention of prisoners of war captured by the Southerners. Omitting any reference to the minor prisons, I shall dwell here only on Andersonville and Libby prisons. With the sectional controversy as to the inhumane treatment of these prisoners by their captors, this history has no connection. Yet, making due allowance for possible brutality (perhaps a natural consequence of a bitter internecine war), the mortality rate in these two prisons was, indeed, staggering. It is generally known, of course, that the South was in the midst of a desperate struggle for governmental existence; that the ordinary industries of the entire section had been largely paralyzed, and that corn was one of the chief (if not absolutely the only one) article of diet. In the two prisons referred to, both situated in agricultural states, corn was necessarily generally used, and the bread furnished the prisoners is described as having been of very poor quality. Under these circumstances, the inquiring mind naturally asks if pellagra, unrecognized and unheeded, did not prevail in these prisons to a great extent. This line of thought might well be pursued with profit by other students of historical medicine; and I hope that as a result of the suggestion further inquiries of this nature will be made for the benefit of the profession and the public in general.

[2] Brown and Carruthers: *Practitioner*, London, May, 1906

[3] Brown, R. D., and Low, R. C.: Edinburgh Med. Jour., September, 1909.

Dr. John P. Gray, of Utica, N. Y., and Dr. Tyler, of Somerville, Mass., at the annual convention of American Asylum Physicians, held in Washington, D. C., in 1864, reported two cases of suspected pellagra,[4] in each of which there were mental symptoms.

We hear no more of the disease until 1902, when Drs. S. Sherwell, of New York, and H. F. Harris, of Georgia, each reported a case. Between the first and second authentic accounts of the disease in the United States a period of thirty-eight years elapsed, and it is reasonable to infer that during that interval the disease was either erroneously diagnosed or unrecognized. Dr. Isaac M. Taylor, of Morganton, N. C., has seen seven positive cases of pellagra since 1905, and states that, reviewing his twenty-three years' care of the insane, he is now convinced that he has seen similar cases within that period. This is also the experience of Dr. J. Taylor, of Columbia, S. C. The two Taylors, one from North Carolina and the other from South Carolina, have expressed the opinion that the so-called "scrofulous" negroes were really pellagrous. W. S. Thayer, of Baltimore, recalls having seen a case in 1905 which he is convinced to-day was pellagra.

In 1907 a sporadic case of pellagra in Texas was reported by Dr. T. C. Merrill, of Colorado, Texas. During the same year the disease was recognized and reported independently by Dr. J. W. Babcock, superintendent of the South Carolina State Hospital for the Insane, and Dr. George H. Searcy, superintendent of the Alabama State Hospital for Colored Insane. In 1908 the disease was identified by two South Carolina physicians (Babcock and Watson, of Columbia) while in Italy, where they had gone for the purpose of studying the disease. They recognized the disease independently of each other. Within the past eighteen months, reports as to the occurrence of the disease show it to be of alarming frequency in the Carolinas, Georgia and Alabama. The Public Health Reports of the United States issued by the Treasury Department, vol. xxiv, No. 25, contains a table showing about 1,000 known cases of pellagra scattered in thirteen states. More than half of these have been reported from asylums or similar institutions. Since the inception of the present discussion a number of cases are coming to light in Florida, Louisiana and Mississippi. Sporadic cases have been reported from Texas, Arkansas, Kansas; and in the Eastern states the disease has been observed by various physicians in New York and Pennsylvania, and in the southern states of Maryland and Virginia. Dr. B. K. Ashford has recorded one case occurring in Porto Rico, and Dr. J. A. Hayne has seen two cases in the Panama Canal Zone. C. H. Lavinder makes a conservative estimate of at least 1,500 cases since 1906. He recently found from forty to fifty cases in the Illinois State Hospital for the Insane, at Peoria, Ill. From the testimony of the staff of that institution it now appears that the disease has existed for the last eight years and was only recently recognized.[5]

I have endeavored to trace briefly (1) the meaning and origin of the term pellagra; (2) the extent and location of the disease; (3) the labors of the foremost students of the disease in the United States. I have purposely refrained from touching the etiology of the disease, and for this phase of the subject would refer the reader to Sanbon's exhaustive essay.[6] Every student of the malady will gain much valuable knowledge and be amply repaid for his time by a thorough perusual of the valuable monograph on the disease by C. H. Lavinder.[7]

In the preparation of this paper I have consulted all the authorities accessible to me and have utilized whatever seemed essential to the discussion. No history is ever absolutely "original," but each must be culled from many sources. I do not assert that this essay is the result of years of painstaking personal investigation, but rather a summary of the works of some of the greatest students of the disease.

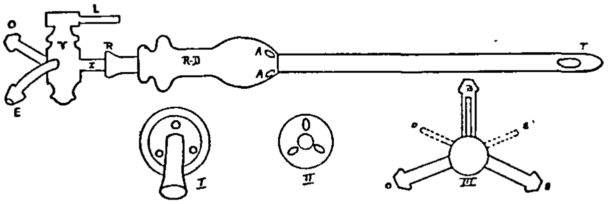
Clinical Notes

A NEW DEVICE FOR RECTAL ANESTHESIA

F. HOEFFER McMECHAN, M.D.
Anesthetist to St. Mary's Hospital
CINCINNATI, OHIO

Thus far in rectal anesthesia two phases of the administrative technic have given trouble: (1) the simultaneous supply of oxygen with the warmed ether vapor or its independent use after the completion of the operation to facilitate recovery, and (2) the accumulation of gas in the bowels without any satisfactory method of egress.

The accompanying sketch of a device for use in conjunction with the Cunningham apparatus shows how these troublesome phases have been overcome.



Device for rectal anesthesia.

V is the Haslam bladder-washer with an additional hole bored into the core at the opening O, and a groove cut across the core for one-third of the distance from the exit tube to the inlets, thus making a three-way valve. With the lever at I both oxygen and ether are admitted; the movement of the lever toward E gradually shuts off the oxygen and admits ether vapor alone; the lever moved toward O gradually shuts off the ether vapor and admits only oxygen. The tube from the oxygen water-bottle is attached at O and the tube from the anesthetic apparatus at E. The supply of oxygen and ether separately or in combination can then be regulated by the movement of the lever at the discretion of the anesthetist.

The three-way valve is connected with a flexible rectal tube (RT, French 27, American 18), which fits into an especially prepared rectal dilator (RD). This dilator is metal and of the self-retaining type. The caliber of the central channel is just large enough to admit the rectal tube on pressure, thus allowing an elongation or shortening of the tube projected into the bowel, which projection averages, according to Cunningham, between ten and twelve inches. Another series of channels extend from the tip to the butt of the dilator. These channels serve as air-vents for the egress of accumulated gases in the bowel and dispense with the necessity of introducing the finger into the rectum during the course of anesthesia to facilitate the egress of the accumulated gases.

---

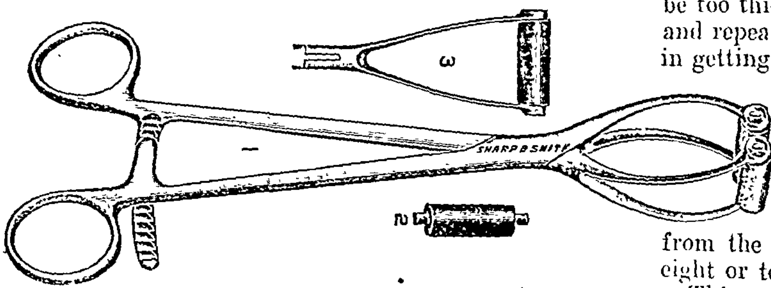
A NEW VISCERA FORCEPS

MILTON R. BARKER, M.S., M.D.
CHICAGO

In the forceps about to be described the jaws are round, made of steel, and so constructed that they can be removed in an instant by springing apart the supporting frame. Figure 2 represents one of the jaws of the forceps removed from the frame, and Figure 3 is a front view of a jaw section of one of the blades. The jaws are covered with rubber tubing, which projects beyond the frame of the instrument, thus preventing any tissue grasped being injured by it. The frame supporting the jaws is so fashioned that if, after being grasped, any bellying of the tissues takes place, as often does in handling the stomach or intestines, they cannot be injured as they cannot come in contact with the frame.



A new viscera forceps. 1. The complete instrument; 2. one of the jaws of the forceps removed from the frame; 3, front view of a jaw section of one of the blades.

A large or small amount of tissue may be included in the bite of the instrument as the case demands. The force that may be applied is regulated by the pliable steel frames supporting the jaws by the rachet in the handle of the instrument and by the rubber cushion covering the jaws. The greatest force that can be applied will not injure any of the tissues handled. The instrument, when applied, never slips nor loses its hold.

The forceps is made in two sizes. The jaws of the larger being seven-eighths of an inch long, those of the smaller one-half inch long. In other respects they are alike. The larger instrument best serves the purpose when handling the stomach or large intestine; the smaller is better adapted to gall-bladder, small intestine and appendix work.

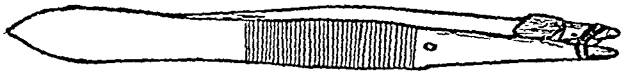
While the instrument was designed for handling the abdominal viscera, I have found it useful in many surgical procedures, when it is necessary to handle organs or tissues without traumatism. I have recently delivered a kidney, with the larger instrument, with great satisfaction. So far I have used only plain, sterile rubber tubing on the jaws of the instrument, discarding the corrugated varieties. It is always best in this instrument, as in all others, with which rubber is used, to sterilize the instrument and tubing in separate vessels; otherwise the instrument is blackened.

4625 Greenwood Avenue.

AN IMPROVISED METHOD OF MAKING FROZEN SECTIONS FOR IMMEDIATE DIAGNOSIS

H. J. RELIHAN, A.B., M.D.
BURR OAK, KAN.

I have recently needed, on the removal of various pathologic tissues, to arrive at immediate diagnosis, and being in the average country office, without microtome and the accompanying conveniences of a city laboratory, I have been forced to improvise some method to meet the conditions.



Specimen of pathologic tissue held in tissue forceps for freezing.

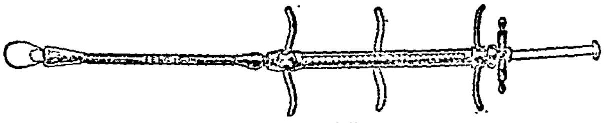
After having removed the tissue I take a small piece, about 1 cm. square, and place it in the jaws of a common tissue forceps about 1 inch from the end, and then wind a small rubber band around the points of the forceps; the tissues are thus held securely, as shown in the illustration. Next I freeze the tissues, which is done with a common tube of ethyl chlorid; after freezing thoroughly I trim off most of the section roughly so that the surface of the tissue is about 2 mm. above the jaws of the forceps. It is again frozen, and a sharp razor, held at a good cutting angle, resting on the jaws of the forceps as a track, is drawn across the tissue. The first section will be too thick, but after freezing the third or fourth time, and repeating the same procedure, I have had no trouble in getting thin sections. The contraction of the forceps blades seems to be so much quicker than the tissue contraction that the projecting portion is about the right thickness for a section. By going through this procedure I have had no trouble in getting very thin sections, which answered my purpose perfectly. The time from the live tissue until the mount is made is about eight or ten minutes.

This could not be recommended where the slide is to be made for a permanent specimen, but it very well answers the purpose of a temporary mount for an immediate diagnosis, the same technic being used for mounting as in any frozen section.

A NEW TONSIL-SNARE

ARTHUR J. HILL, M.D.
CANTON, OHIO

This snare consists essentially of a stylet, sliding collar, wheel and cannula, in the upper part of which are two longitudinal slots. The sliding collar is fastened to the stylet by means of a thumb-screw which passes entirely through the collar and stylet. Threads are cut in the stylet only, thus preventing friction on either side and permitting instantaneous tightening of the wire on the tonsillar base, when a few turns of the wheel completes the operation. The illustration shows the mechanism very well.



A New Tonsil-Snare.

Its advantages are its ease, rapidity and certainty of operation, strength and simplicity, and the fact that it cannot get out of order.

604 Courtland Building.

BLUEBOTTLE FLIES AS CARRIERS OF INFECTIONS

W. FOREST DUTTON, M.D.
PITTSBURG, PA.

The bluebottle and blow- or flesh-flies are not so numerous in or about human habitations as the house-fly, yet they are not to be considered a minor factor as a carrier of disease. The *Lucilia cæsor* is the commonest bluebottle or greenbottle fly and is most likely to frequent houses before rain.

Some species breed exclusively on meat, while others may lay their larvæ on meat, open sores, decaying vegetable material, cow manure and undigested human dejecta. The larvæ grow rapidly and attain full size in about five days. They develop into adults in two weeks. The *Sarcophaga sarraceniæ,* which resembles an extra large house-fly, is, perhaps, the most abundant flesh-fly in this country.

The habits, breeding places and nature of these flies make them a tangible factor in the dissemination of typhoid fever. This can best be exemplified by citation of one instance in which such was the case: A bacilli carrier was attacked with acute indigestion and passed particles of undigested meat, etc. The stools were voided or deposited in a privy, standing two feet above the ground, some twenty yards from the dwelling. The stools were passed directly on the ground and were easily accessible to flies.

The flies fed freely on this dejecta and carried infected material on their hairy feet and body to the food used by the household. The result was that four members of the family were attacked at about the same time. Every other avenue for infection, except by flies, was excluded.

The human bacilli carrier, the infected bluebottles, the transmission to the meat (cold sliced) gave, in this particular case (from deductions and conclusions), the source of infection.

THE LATER STAGES OF EXPERIMENTAL MYOCARDITIS

A PRELIMINARY NOTE [*]

MOYER S. FLEISHER AND LEO LOEB
PHILADELPHIA

The investigators who employed frequently repeated intravenous injections of adrenalin into rabbits for the production of aortic lesions commonly noted at the autopsy not only blood-vessel but also myocarditic changes. So far it has not been possible to study the succeeding stages in the development nor the ultimate outcome of this disease.

A short time ago we found that one single injection of adrenalin (0.2 c.c.) cause in many cases a myocarditic lesion and that one injection of a combination of a relatively small dose of adrenalin and spartein or caffein produced macroscopic changes in the heart of the rabbit in about 60 per cent. of the cases and microscopic changes in almost all of the animals. We concluded therefrom that a cardiac and not an aortic lesion was the typical effect of intravenous injection of adrenalin. This enabled us to establish the sequence of events in the development of the myocarditic lesions. The change taking place during the first six weeks after the injection of adrenalin we have described elsewhere.[1] Since then we have studied later stages, namely, the period six to fifteen weeks after the injection, and here we wish to state briefly the main result of these studies, which we believe to be of interest from the point of view of human pathology also.

While up to approximately six weeks after the onset of the disease we found in many hearts very pronounced gross lesions, yellow discoloration, stiffening and loss of pliability, thickening of the wall of a part (sometimes the major part) of the left ventricle, we were surprised to see how completely such apparently far-going gross lesions can retrogress within a relatively short time.

The microscopic changes, which consist in the first period of the disease (comprising the first six weeks) principally of a considerable enlargement of the muscle fibers, increase of the connective tissue and some degenerative changes of the muscle fibers, show likewise retrogressive changes in the following period from six to fifteen weeks after the onset of the disease. It is very rare to discover vacuolization of the muscle fibers; the enlargement of the muscle fibers is considerably less marked; the appearance of the double nuclei in the muscle becomes much rarer. Now, however, at some places we find tracts of rather dense fibrous tissue and occasionally infiltration of small cells.

There can therefore be no doubt that very pronounced healing processes take place with a surprising rapidity and hearts which a few weeks after the primary injury showed marked lesions to the naked eye appear in many cases quite normal a few weeks later. Thus relatively small lesions can be detected in such cases only through microscopic examination.

It will be of great interest to follow the fate of the fibrous bands which develop in such hearts. We hope to be able to report on this question at a later date.

A SMALL LOCALIZED EPIDEMIC OF AMEBIASIS

WILLIAM ALLAN, A.B., M.D.
Professor of Parasitology, North Carolina Medical College
CHARLOTTE, N. C.

In June, 1909, a person with amebiasis moved into House 3 on North Johnson street. The five households in this row all used water from the well between Houses 1 and 2. This is a surface well, about twenty-five feet deep and in no way protected from surface drainage. The privies are all directly back of the houses, on higher ground than the well, at a distance varying from 50 to 150 feet.

On August 16 three people in House 5, three in House 4, and one each in Houses 3, 2 and 1 complained of sore mouth; some of them had diarrhea, some of them only intestinal fermentation without diarrhea. These sore mouths had all developed within the past two weeks and all presented the same appearance—dry red erosions at the angles of the mouth with a dry, brick-red, bald, fissured tongue.

When the first one was seen, pellagra was suspected; when representatives from every house on the street presented themselves, it became evident that the trouble was epidemic, and amebic dysentery was the next most natural thing to suspect. This suspicion was heightened when a history of recently acquired diarrhea was obtained from about half the sufferers.

---

[*] From the Laboratory of Experimental Pathology, University of Pennsylvania.

[1] Fleisher, Moyer S., and Loeb, Leo: Experimental Myocarditis, Archives of Internal Medicine, February, 1909, iii, 78.

On August 17 a microscope was carried out and *Entamœba histolytica* found in the stools of two patients in House 5 and in one of the two patients examined in House 4. The other patient in House 5, and the patient in House 3 (son of the original patient), together with the patients in whose dejecta amebæ were found, all showed eosinophilia. Unfortunately, it was impossible for a man in general practice to make a routine examination of the blood and feces of every one living in the five houses. Within three weeks three of these households had moved, one to another mill section of Charlotte, one to another North Carolina town, and one to parts unknown.

The dysenterics at once attributed their sickness to the well used by all in common. They said that the water smelled bad, and were unanimous in saying that it "griped" them. A specimen of this water, with scrapings from the well bucket, was taken at once. This showed algæ, vorticellæ, several varieties of low animal life that were unknown to us, and amebæ corresponding in size and appearance to the *histolytica*. We cannot say definitely that these were pathogenic amebæ. The use of the well-water was stopped at once, and in the families we have been able to keep track of, no new cases have developed. The owner of the property very humanely put in a safe water-supply.

In view of the wide-spread prevalence of amebiasis throughout the South, it is imperative that the local health authorities take some steps to abolish the careless and almost universal custom of soil pollution that prevails in this section.

DISAPPEARANCE OF A LARYNGEAL GROWTH, PROBABLY CARCINOMA, WITHOUT TREATMENT

JOSEPH B. GREENE, M.A., M.D.
BIRMINGHAM, ALA.

The following case presents some points of interest worthy of reporting, as it seems to correspond with a certain class of cases recently referred to by Jonathan Wright.[1] Till Wright's paper appeared, I had been almost convinced that my case was one of benign papilloma, in spite of the fact that the growth had all the macroscopic appearances of early malignancy. The opinion that the growth was malignant was shared by Dr. E. Fletcher Ingals, who saw the patient in June, 1908. Now I am of the opinion that the tumor was carcinoma, but disappeared without treatment. As to this fact, however, we can never be sure, as the patient declined to have a specimen removed with a view of prompt laryngectomy, or, at least, laryngotomy.

Patient.—A physician and friend, aged 50, first consulted me May 2, 1908. He had always enjoyed good health; had been a hard-worked physician for about twenty years. He smoked cigars and pipe moderately. There was no history of syphilis or tuberculosis. Family history negative, except that the patient's paternal grandfather died, probably of carcinoma. The patient's present condition was that of a fairly well-nourished man, though he looked a little older than 50. Three months before examination patient began to complain of slight pain in the throat, worse at times, when larynx was in a certain strained position.

Examination.—Chest negative. No glandular enlargement on neck or elsewhere. No cough. Hoarseness very slight, hardly noticeable. Markedly deviated nasal septum. Some nasopharyngeal catarrh present. A small growth over the center of the left vocal chord, about the size and shape of a small grain of wheat, attached to the upper and inner side of the chord; not pedunculated; surface somewhat uneven, and attached base distinctly red.

Course of Disease.—On May 19, 1908, there seemed to be some increase in size. On June 4, patient was seen by Dr. Ingals in Chicago, who pronounced the case probably carcinoma. He advised the use of tuberculin for diagnostic purpose, and if no reaction occurred, then a removal of a fragment of the growth for examination. If found to be carcinoma, he advised laryngectomy, or at least laryngotomy. In this advice I coincided. At this time (June 4) I again advised the patient's return to Chicago for examination and operation, if necessary. Patient seemed to agree as to the probable diagnosis, but preferred to continue his work as long as possible and to avoid a severe operation, which would probably cause serious impairment or entire loss of his voice. The tuberculin gave the patient unpleasant symptoms, such as headache and dizziness, and was, therefore, discontinued. The small dose gave no reaction either in appearance of the growth, or a rise of temperature. On Oct. 7, 1908, patient reported at my office for examination, and to my surprise and delight there was no sign of the growth to be seen.

While the result of the above case was very satisfactory without surgical measures, far be it from my mind to recommend delay or expectant treatment of such growths.

CECOSTOMY—THE OPERATION OF CHOICE FOR TEMPORARY DRAINAGE OF THE COLON

C. C. ALLISON, M.D.
OMAHA

For that class of cases, in which colostomy is indicated, for physiologic rest of the colon, the problem of efficient drainage is paramount, but the subsequent closure of the opening in the bowel is a surgical problem hardly secondary in importance to successful drainage.

Appendicostomy can not be accorded more than a limited field of usefulness, because in a great majority of cases it is diversion of the fecal current, rather than irrigation, that is the essential therapeutic aid; nor will the mere opening of the ascending colon afford sufficient drainage in the more severe types of colitis.

It is my experience that cecostomy can be so accomplished by rotating the cecum upward and outward and making the opening opposite the ileocecal aperture, then not only efficient drainage is accomplished, but, what becomes most practical in the subsequent management, the closure of the opening in the cecum can be done with the utmost ease by the surgeon and with perfect safety to the patient.

It is true that a part of the cecum is sacrificed, but the danger of stricture is eliminated, a complication which is actual in case of simple colostomy, without a spur, and the dangers of an anastomosis is avoided, as would be the case with the Maydl tube.

Cecostomy has appealed to me, therefore, as being the operation of choice, when the fecal current is to be temporarily diverted from the colon, both because it affords more efficient drainage and because the closure of the opening becomes a minor surgical procedure.

A Model City.—If we had a national department of health it could assist in making our national capital, the city of Washington, into a model sanitary city, free from insanitary tenements and workshops, air pollution, water pollution, food pollution, etc., with a rate of death and a rate of illness so low as to arouse the attention of the world.

New and Nonofficial Remedies

SINCE THE PUBLICATION OF THE BOOK "NEW AND NONOFFICIAL REMEDIES, 1909," THE FOLLOWING ARTICLES HAVE BEEN ACCEPTED BY THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION. THEIR ACCEPTANCE HAS BEEN BASED LARGELY ON EVIDENCE SUPPLIED BY THE MANUFACTURER OR HIS AGENT AND IN PART ON INVESTIGATION MADE BY OR UNDER THE DIRECTION OF THE COUNCIL. CRITICISMS AND CORRECTIONS TO AID IN THE REVISION OF THE MATTER BEFORE PUBLICATION IN THE BOOK ARE ASKED FOR.

THE COUNCIL DESIRES PHYSICIANS TO UNDERSTAND THAT THE ACCEPTANCE OF AN ARTICLE DOES NOT NECESSARILY MEAN A RECOMMENDATION, BUT THAT SO FAR AS KNOWN IT COMPLIES WITH THE RULES ADOPTED BY THE COUNCIL.

W. A. PUCKNER, SECRETARY.

(*Continued from page 869*)

SOLUBLE FERRIC ARSENITE—Ferri Arsenis Solubilis.—Ferric Arsenite and Ammonium Citrate.—Ferric Arsenite made soluble by the addition of ammonium citrate.

Soluble ferric arsenite occurs in green scale, easily soluble in water; it contains 1.06 per cent. arsenic, equivalent to 1.4 per cent. arsenous oxide, and iron, equivalent to from 15 to 18 per cent. elementary iron.

Actions and Uses.—Soluble ferric arsenite is a hematinic said to be particularly indicated in anemia, complicated with malaria; in pernicious anemia and in pellagra.

Dosage.—0.03 to 0.065 Gm. (½ to 1 grain). It may be given by subcutaneous injections in the gluteal region in doses of 0.03 Gm. (½ grain) dissolved in 1 Cc. (15 minims) of water every two or three days.

Non-Proprietary Preparations:

Ampules Iron Arsenite Solution S. & D.—Each Ampule is said to contain 0.06 gm. (1 grain) of soluble iron arsenite, dissolved in 1 c.c. (16 minims) of distilled water, representing closely 0.00092 gm. (1/70 grain) of arsenic trioxide and 0.0092 gm. (1/7 grain) of metallic iron.

Prepared by Sharp & Dohme, Baltimore, Md.

ANTIPYRINE SALICYLATE—Antipyrinæ Salicylas.—(See N. N. R., p. 24).

Proprietary Preparation:

SALIPYRINE.—A name applied to antipyrine salicylate.

Manufactured by J. D. Riedel Aktiengesellschaft, Berlin, Germany. (Riedel & Co., New York.) U. S. patent No. 444004. U. S trademark No. 19043.

PARA COTO—(Coto[1]).—The bark of an undetermined South American tree, probably a species of Cryptocarya.

Para Coto occurs in pieces which are of considerable size and thickness, 30 cm. (12 in.) wide and 1.5 cm. (⅝ in.) thick. The outer surface is of reddish-brown or cinnamon-brown color. It is sometimes fissured longitudinally and transversely, and sometimes nearly smooth, with occasional patches of whitish cork. The inner surface is coarsely striated. It breaks with a fibrous, splintery fracture, and the smoothed transverse section exhibits a thin, brown cork within, which is a narrow cortex separated by a line of sclerenchymatous cells from *the very thick bast*, which is well characterized by the presence of abundant groups of sclerenchymatous cells. The odor is spicy and characteristic, the taste aromatic and pungent. (Para coto is exported from Para at the mouth of the Amazon, and should therefore be called Para coto and not paracoto.)

The chief constituent of Para coto is paracotoin, an indifferent crystalline, bitter principle alo[illegible] [illegible]l hydrocotoin protocotoin, methyl [illegible] phenyl coumalin, piperonylic acid, vo[illegible]

Para coto is distinguished [illegible] of nitric acid on the ether extractive matter. In the case of Para coto the result is the formation of a yellow color and in the case of coto a red color appears.

Actions and Uses.—Paracotoin is irritant to the gastrointestinal tract and is similar to cotoin but is weaker. Para coto is used like coto as an appetizer and for diarrhea and dysentery and similar disorders.

Dosage.—0.05 to 0.5 Gm. (1 to 8 grains).

PARACOTOIN.—A principle, $C_{12}H_8O_4$, from Para coto.

Para coto is extracted with ether and the ether extract distilled. The residue is fractionated by repeated crystallizations from hot alcohol. The first body to separate out is paracotoin.

Paracotoin is a pale yellow, crystalline body, neutral in reaction, tasteless and odorless, melting at 149°-152° C. (300.2°-305.6° F.). It is difficultly soluble in water, but easily in ether, chloroform and boiling alcohol. Concentrated sulphuric and nitric acids dissolve it, forming a yellowish-brown solution. On boiling with a solution of caustic alkalies, a colorless crystalline body, melting at 82°-83° C. (179.6°-181.4° F.), and having the odor of coumarin is formed; this body is acetopiperon (paracumarhydrin) $C_9H_8O_3$ or $C_6H_3\ O_2CH_2.CO.CH_3$, and paracotoic acid $C_{12}H_{10}O_5$ a yellow amorphous mass melting at 108° C. (226.4° F.). Paracotoin fused with potassium hydroxide yields principally piperonylic acid $C_8H_6O_4$.

1 Gm. of paracotoin shaken up with 10 Cc. of fuming hydrobromic acid forms a semi-solid mass of yellow crystals, which on drying over potassium hydroxide lose hydrobromic acid. This residue decomposed with water and recrystallized forms paracotoin, recognized by its crystalline form and melting point.

By gradually adding about 1 Gm. paracotoin to about 10 Cc. concentrated nitric acid, a red-brown solution will result, which, when heated for a short time on the water bath and cooled, deposits a yellow crystalline mass. This product recrystallized from acetone and then from benzene or glacial acetic acid forms golden yellow crystals, melting at 195° C. (323.0° F.). This body is dinitro paracotoin, probably of the formula $C_{12}H_6\ (NO_2)_2O_4$.

An excess of bromine added to a 10 per cent. solution of paracotoin in chloroform cooled to 0° C. produces a deep yellow precipitate, which loses hydrobromic acid, and when recrystallized from alcohol forms the mono-bromide of paracotoin, melting at 200°-201° C. ($C_{12}H_7BrO_4$).

Actions and Uses.—See para coto.

Dosage.—0.06 to 0.18 Gm. (1 to 3 grains).

MERGAL.—Mergal is a mixture of 1 part of mercuric cholate and 2 parts of albumin tannate put in capsules, each capsule said to contain approximately 0.15 Gm. (2¼ grains) of mergal equivalent to 0.05 Gm. (¾ grain) mercuric cholate and 0.1 Gm. (1½ grains) tannin albuminate. Mergal contains approximately 4.4 per cent. mercury.

Mercuric cholate is prepared by a patented process, mixed with albumin tannate, and inserted into gelatin capsules in the usual way.

Mergal is a yellowish white, loose, somewhat light powder, insoluble in water and alcohol and almost insoluble in solution of sodium chloride.

When 0.1 Gm. of mergal is shaken with a few drops of saturated solution of cane sugar and underlaid with concentrated sulphuric acid, a purplish red to reddish violet zone is produced.

If 0.2 Gm. of mergal is warmed on the water bath with 10 Cc. of hydrochloric acid for about fifteen minutes and the evaporated water replaced after cooling and filtering, there results a colorless or slightly yellowish solution which gives a black precipitate with solution of hydrogen sulphide. The same filtrate gives with a drop of stannous chloride solution an immediate precipitation of metallic mercury.

Mergal should leave no weighable residue on incineration.

0.2 Gm. of mergal boiled for one minute with 20 Cc. of water gives a clear filtrate which is colored dark violet on the addition of a drop of solution of ferric chloride.

0 1 Gm. of mergal when heated with a mixture of 5 Cc. of concentrated sulphuric acid and 5 Cc. of water to boiling, produces a turbid reddish solution. The filtrate after dilution with 3 to 4 parts of water and the addition of a drop of solution of copper sulphate gives on careful underlaying or on mixture with an excess of sodium hydroxide solution an evanescent violet-red color. Mergal should be protected from the light.

Actions and Uses.—Mergal is said to pass through the stomach without decomposition and to be decomposed into its constituents in the small intestine, where the mercury is quickly absorbed into the blood and excreted through the kidneys. It is said to be useful in all forms of syphilis and in the para-syphilitic affections, such as diabetes and general paralysis. It is also said to be useful for the chronic intermittent treatment according to the method of Fournier and Neisser.

Dosage.—One capsule three times a day after meals, gradually increasing to two capsules five or six times a day.

Manufactured by J. D. Riedel Aktiengesellschaft, Berlin, Germany (Riedel & Co., New York). U. S. patent No. 811193. U. S. trademark No. 53919.

N. N. R. ARTICLES AMENDED

ADRIN SOLUTION 1-500

The H. K. Mulford Co. has informed the Council that the epinephrine used in making adrin solution 1-500 (see N. N. R., 1909, p. 53) is no longer made by the method of Abel, but by the method of v. Fuerth (Hoppe Seyler's Zeitschrift für physiologische Chemie, vol. xxvi, p. 15).

ARTICLES ACCEPTED FOR N. N. R. APPENDIX

Manhattan Eye Salve Co., Owensboro, Ky.:

Argyrol Ointment (M. E. S., Co.).—An ointment said to consist of argyrol 10 per cent.; hydrous wool fat, 25 per cent.; white petrolatum, 65 per cent. Put up in collapsible tubes, for application to the eye.

Dionin Ointment (M. E. S. Co.).—An ointment said to consist of dionin 5 per cent.; white petrolatum, 95 per cent. Put up in collapsible tubes, for application to the eye.

Holocain and Adrenalin Ointment (M. E. S. Co.).—An ointment said to consist of holocain 1 per cent.; adrenalin chloride, 4 per cent.; hydrous wool fat, 10 per cent.; white petrolatum, 85 per cent. Put up in collapsible tubes, for application to the eye.

Sharp & Dohme, Baltimore, Md.:

Compressed Tablets Atoxyl and Iron.—Each is said to contain atoxyl 0.02 gm. (1/3 grain) and ferrous lactate 0.06 Gm. (1 grain).

(*To be continued*)

---

[1] While commercially, Para coto and coto are sold indiscriminately, botanists make a definite distinction between them

Therapeutics

ALCOHOL

In spite of the many discussions on this subject, the question is still open as to whether alcohol should ever be used as a therapeutic agent.

The whole general discussion of alcohol is grossly unfair to it as a component part of the materia medica. Who would think of describing the poisonous effects of large doses, or the dire effects from the prolonged use, of some drug of the Pharmacopeia other than alcohol, when the discussion was on the value of that drug as a therapeutic measure? Large doses of alcohol are harmful; repeated large doses are pernicious; and an alcohol habit is ordinarily bad physiologically, pathologically, and morally. But if we are to be fair to alcohol as a drug we must discuss it as we would any other drug, viz.: describe its physiologic action in therapeutic doses, the indications that it may therefore meet, and the undesired symptoms and conditions that it may successfully combat. Next we must discuss the possibility of some other drug acting as well to meet these indications. In other words, are there other drugs that act physiologically similar to alcohol? Next, does this drug cause the alcohol habit if used therapeutically, and, if so, how frequently?

To answer the last question first, very rarely does any patient acquire the alcohol habit from its medicinal use during an acute disease. If such has occurred, it was because of a tendency to the habit, inherited or acquired, and it was only a question of opportunity or environment for it to develop. A physician should not be excused, except perhaps in rare instances, and that generally in old age, who orders alcohol for a chronic condition, and the legitimate use of alcohol in chronic conditions is so limited as to be hardly a subject for discussion.

We then come to the physiologic action of alcohol that is desired or can be utilized to combat diseased conditions or undesired or dangerous symptoms. To discuss this properly, alcohol must be classified therapeutically. The objects for which it has been used, and its physiologic action, have caused it to be classed as a stimulant, a vasodilator, a narcotic, a hypnotic, and a stomachic.

It is a mistake to class alcohol as a stimulant, as this carries with it a mistaken idea of the physiologic action. While it may stimulate the heart and raise arterial pressure momentarily, its secondary effect is a cardiac depressant and a vasodilator. The only time when alcohol is a stimulant is in acute cardiac failure, and then it is stimulant to the heart only before its absorption, reflexly from the irritation, when taken in concentrated solution, of the mucous membrane of the mouth, pharynx, esophagus and stomach, the rectum, if it is administered as an enema, and the tissues, if it is given hypodermatically. To obtain such stimulation it is, of course, a recognized fact that the alcohol must be a strong preparation, either brandy, whiskey, gin, rum, or champagne. This reflex irritation through the vasomotor center temporarily raises the blood pressure, and perhaps through the accelerator nerves stimulates the heart. To keep up this stimulation, another dose must soon be given, in from fifteen minutes to half an hour or an hour, depending on the prolongation of the heart weakness. The dose of alcohol for such stimulation should be small in order that the results from the subsequent absorption will be the minimum, as the vasodilator effects are not desired. If the alcohol is administered too frequently, it accumulates in the system before the previous doses can be burned or eliminated, and then to obtain stimulation it will be necessary to give a larger, concentrated dose to cause sufficient irritation and stimulation to overcome the depression of the previous doses. The result of such medication is very obvious. Soon the vasodilatation is increased, the heart is depressed, the nervous system more or less paralyzed, and depression is added to depression; and the treatment is vicious. Consequently, the only excuse for using alcohol in any form as a cardiac or circulatory stimulant is when the depression or syncope is short lived, or perhaps as a primary stimulant in acute collapse. In any prolonged circulatory depression alcohol is *contraindicated.*

In conditions of prolonged fever in which alcohol is given no more frequently, for any length of time, than every three hours, one dose is probably eliminated before the next one is administered. The real value of its administration is due to the dilatation of the peripheral blood vessels, which equalizes the circulation and reduces the temperature.

As an actual narcotic alcohol is rarely used, and should not be so used. As a secondary effect of therapeutic doses its general tendency to quiet nervous irritability in seriously ill patients may be desired and utilized, but to use alcohol as a narcotic directly when other symptoms do not indicate its use is ordinarily inexcusable. In serious feverish conditions undoubtedly the narcotic action of alcohol quiets a patient who is highly alert to his danger, and may be of distinct advantage, as mental worry and anxiety are aids and abettors of disease which should be overcome by any legitimate means.
